INJURIES TO THE ANKLE JOINT AND THEIR TREATMENT.

By MORRIS B. COOPERMAN, M.D.,

PHILADELPHIA, PA.

INSTRUCTOR OF ORTHOPEDICS, UNIVERSITY OF PENNSYLVANIA
GRADUATE SCHOOL.

INJURIES to the ankle joint are very common, contusions and sprains being the lesions usually seen. When the bones of the leg are fractured in the lower third, or when the foot has been severely injured, there is usually an associated trauma at the ankle joint. The most common condition, however, that the surgeon is called upon to treat in this region is a sprain, a term which is popularly associated with this joint.

A sprain of the ankle may be defined as a sudden twisting or wrenching of the relaxed foot, in which there may be a transitory dislocation inward, outward, anteriorly or posteriorly. The force may be of such a degree as to injure the synovial membrane, to rupture some of the fibers of the muscles, to strain tendons and tendon sheaths, to rupture ligaments, to separate articular surfaces, or even to tear off chips of bone. Sprains of this joint are of various degrees, depending upon the character of the violence. Being the most dependent of the large joints of the body and bearing its weight, any disturbance in equilibrium, if the muscles of the foot be off guard, will produce instability, and twists of the foot result. In lateral twists, the weight of the entire body, transmitted through the leverage of the whole lower extremity, is received at the ankle, inducing stress at its supports. Again, owing to its dependency, it is the joint that is most frequently injured by falling objects or in falls from a height. The majority of ankle sprains are produced when the muscles guarding it are relaxed. The muscles that surround the joint, by their tonicity, help maintain the normal alignment and stability of the articulating surfaces. Without muscular support, this joint would be flail in character. Ligaments alone do not maintain stability. They bear the brunt of the stress, however, when violent force is applied to the relaxed foot.

Anatomy.—The ankle joint is a true hinge joint, the articulation being between the upper cartilaginous surface of the astragalus and the inferior articular surfaces of the tibia and fibula. The ligaments supporting this joint are the capsular and the two lateral ligaments with their divisions.

The capsular ligament is simple in arrangement and it surrounds the ankle joint. It arises from the

front of the tibia, near its lower border, and from the front of both malleoli. Posteriorly, it arises from the posterior border of the malleoli and the tibia. The inferior insertion surrounds the articular surface on the top and side of the astragalus. The fibers of the capsule in front and back are thin and not strong.

The internal lateral or deltoid ligament is an extremely thick and strong part of the capsule, arising from the posterior border and tip of the internal malleolus, running downward and backward to the astragalus below the inner surface and to the sustentaculum tali. The anterior part of this ligament runs to the inferior calcaneoscaphoid and superior astragaloscaphoid ligaments.

The external lateral ligament consists of three bands which radiate from the external malleolus, while only two are part of the capsule. The anterior band passes forward and inward from the front border of the malleolus to the astragalus, in front of the lateral articular surface. It is made tense in plantar flexion. The posterior band arises from the hollow on the inside of the tip of the outer malleolus and is attached to the astragalus, behind the posterior outer angle of the articular surface. It is the band made tense in dorsal flexion of the foot. With the transverse tibiofibular ligament, it strengthens the back of the capsule. The middle band, more superficial, runs downward and backward to a faint tubercle on the outer side of the os calcis. It restrains certain motions of the astragalus on the calcaneum.

The action of the numerous muscles crossing the ankle joint is greatly to strengthen it and to prevent any giving between the bones when the ligaments are not stretched to the utmost. The foot is held firm and immovable by the tension of the posterior ligament and of the posterior and middle division of the external lateral ligaments, especially by the strong posterior part of the internal lateral ligament. The annular ligaments of the ankle joint are of importance in that they help maintain the various tendons that cross the ankle joint in position.

Etiology.—Ankle sprains, in the majority of instances, are produced while in the act of walking. The unguarded foot may be caught in a piece of carpet and the weight of the body causes it to twist, or in going down a flight of stairs the foot, in its descent, may turn under and be wrenched. Falls from a height, the person landing on his feet, may produce lacerations of ligaments, tendons, etc., in the region of the ankle. Sometimes heavy objects fall upon the extended foot, producing injuries to this joint.

The shoe may be considered a factor in the causation of a number of these injuries. The French heel so commonly worn by women is a predisposing cause, and very often a direct factor in sprains of the ankle. The high and narrow heel produces instability of the foot, and women are particularly prone to ankle sprain. A shoe with a properly laced or buttoned upper is a good protection against lateral play of the ankle. It affords support to it. It has been the observation of the writer that ankle sprains are less frequent when shoes of this type are worn.

Sprains are common between the ages of fifteen and forty. They are unusual in small children and the aged.

Pathology.—Any part of the ankle may be traumatized. The character and type of injury depends upon the degree of violence, its direction and the position the foot was in in relation to the leg when injured. If the foot is plantar flexed at the time the injury is sustained, the most likely seat of the trauma is in back and front of the ankle joint. If twisted inward, the external lateral ligament and structures in back of the external malleolus bear the brunt of the stress. If the foot is twisted outward, the internal lateral ligament and the structures around the internal malleolus are injured.

Severe twists of the ankle joint produce laceration or stretching of the soft structures that hold the joint in alignment. The ligaments may be torn or stretched, muscle tendons may be torn from their attachment, the synovial tissues may be bruised and lacerated, vessels and nerves may be ruptured in continuity. The articular surfaces of the ankle in severe injuries may be traumatized. Usually there is a bloody exudate into the joint, its quantity depending upon the degree of the violence. After the blood has been absorbed, there may be organization of blood clot into fibrous tissue, producing adhesion between joint surfaces. The joint space is distended and the lower extremity of the injured side is longer than its opposite fellow. In a sprain fracture there may be a chipping of bone from either of the malleoli, or from the upper margin of the astragalus.

The areolar tissue on the dorsum of the foot, anterior to the external malleolus, is usually the first part of the foot to show evidence of injury to the external lateral ligament. It is the part showing the greatest degree of swelling after trauma.

The external lateral ligament is most frequently injured. In a series of 500 cases of ankle injuries, it was found that the external ankle was the site of trauma in about 70 per cent. of the cases. This greater frequency may be explained on anatomic grounds. In looking through the literature on this subject I have found that no explanation has been given for the above. The reasons are as follows: *First:* Unguarded muscle control, being an important factor in sprains, it is seen that of the two sides of the ankle, the outer has fewer muscles in relation to it. On the inner side of the ankle and foot are both tibials, the extensor and flexor of the large toe. The unbalanced arrangement of muscle control predisposes, therefore, to sprains. *Second:* The deltoid ligament supporting the inner side of the ankle is short, thick and very tough. It is almost impossible to tear this ligament

without taking with it some of the periosteal attachment. The external lateral ligament is divided into three portions, only one of which is strong, the middle division. This fact makes the external ankle less firmly protected against lateral stress. *Third:* The inner side of the ankle and foot present a stronger chain of bones upon which the weight is borne than the outer. When one examines the bony foot, there is a distinct line of cleavage between the stronger or inner side, consisting of the astragalus, scaphoid, the three cuneiforms and the three inner metatarsal bones, and the outer weaker half, consisting of the fourth and fifth metatarsal, the cuboid and os calcis. Theoretically, at least, this line of cleavage of the foot, dividing it into a weaker outer half and stronger inner half, may be considered a factor of unbalance, the external supports giving way in disturbed body equilibrium. *Fourth:* In the act of walking, weight is first borne upon the heel. Then it shifts to the outer border of the foot and finally upon the ball of the foot. When there is any disturbance in equilibrium, the outer side of the foot, receiving the body weight first, being unsupported by muscle tonicity, the tendency of the foot will be to turn under and inward.

Symptomatology.—Sprains are of various degrees, from the mild cases with very little disability, to the severe cases with rapid effusion and prompt disability. In the milder cases the symptoms are very often late in making their appearance. Three or four hours may elapse between the time in which the trauma was sustained until disability ensues. In the interval many of these patients attend to their duties without discomfort. After this period, however, pain at certain regions of the ankle joint, stiffness and some swelling develop. The more severe injuries to the ankle joint are exceedingly painful and troublesome in their consequences. The intensity of the pain is very remarkable when we consider the low degree of sensibility possessed by the ligaments in a normal state. They may be cut or divided transversely without pain, but if stretched in a longitudinal direction, or twisted, so as to tend to separate the articular surfaces, pain of the most intense character is set up at once. The pain is accounted for by injury to the periosteum, which is highly sensitive. At the time of the sprain, a certain amount of blood is effused into the joint cavity and the surrounding tissues, in consequence of which, the limb in a few days becomes discolored for some distance below and above the joint. The sprain is rapidly followed by swelling and inflammation of the joint and surrounding tissues, often very chronic and tedious. As the inflammation subsides, stiffness and pain in using the part sometimes results. Very often the skin over the region of the sprain is hyperesthetic.

It would be of interest to cite a few cases illustrating the various types that one may meet with in practice.

A person slips off a platform and falls upon his heel, a distance of perhaps three feet. His feet and ankle are jarred but he continues at work or walks for three or four hours. Gradually there is developed stiffness and numbness in the joint, aching and some tenderness in front of the ankle. He stops work at the end of this time because weight bearing then has become painful. An examination of this

case shows no special point of tenderness, there is no swelling of any moment, but the movements of the joint are slightly limited. When weight is borne, however, there is pain in the region of the instep and in front of the ankle. In the course of two or three days of rest, this patient recovers, with little or no treatment with the exception, possibly, of the application of home remedies. This illustrates a case of very mild sprain.

A person falls from a moving conveyance and lands either upon the outer or inner border of the foot. The symptoms of this injury come on immediately. Pain is very intense and often these patients faint. Weight bearing becomes practically impossible. The ankle begins to swell very rapidly, and within the course of several hours its contour is obscured. All movements of the foot are associated with pain. An *x-ray* taken of such a traumatized foot may reveal fracture or dislocation. If the *x-ray* is negative as to bony injury, the diagnosis, then, of course, rests upon one thing only and that is sprain.

A workman employed in one of the mechanical departments of a large industrial plant uses a sledge hammer to break up an iron pipe. A piece of this pipe breaks off and with considerable velocity strikes the inner border of the foot at the heel. He feels a stinging pain in the region where the piece of iron struck. He continues at work for several hours, when weight bearing gradually becomes painful and the ankle becomes stiff. An examination of this foot reveals the following conditions: Tenderness on pressure and pain underneath the internal malleolus, severe pain in front of the ankle and beneath the external malleolus. There is very little swelling of the joint. On plantar flexing the foot, there is severe pain in the region of the anterior slip of the external lateral ligament and the anterior attachments of the capsular ligament. Eversion of the foot relieves the pain; inversion aggravates it. When we analyze this injury, we see that the external lateral ligament is the one indirectly traumatized by the violence. The foot was slightly subluxated laterally and the points of attachment of this ligament were put upon a strain. This type of injury, while unusual, from the standpoint of etiology, illustrates the effect of indirect violence upon the supports of the ankle.

A young woman walking upon an uneven sidewalk, gets her foot caught in a hole, the foot is twisted and she falls. This is a very common form of ankle sprain. Disability is immediate and pain is present at the external ankle. In the fall, the foot was inverted and the stress was put upon the external lateral ligament. An examination of this ankle several hours after the injury, revealed some swelling beneath the external malleolus, tenderness on pressure over the injured soft structures, and redness. On inverting the foot, pain is increased. Eversion relieves it. A sprain of the external lateral ligament is diagnosed.

A laborer employed as a dock hand, while unloading a truck, receives a blow upon the heel by several bags falling upon it. The foot, at the time of the injury, was plantar flexed, heel elevated. He continues at work for several hours, when pain and stiffness in the ankle joint develop. He walks with difficulty. An examination of this ankle reveals the

following conditions: There is considerable swelling in front of the ankle joint and on the dorsum of the foot. There is also some swelling in the back of the ankle. Upon plantar flexing the foot, pain is increased. Dorsi flexion relieves it. This is a case of sprain of the capsule at its anterior attachment.

A laborer has his foot caught in a rope and it is violently pulled up. Disability is immediate. He suffers intense pain along the external aspect of the foot and leg. The foot is held stiff and movements of the ankle joint are restricted. There is severe pain at the external malleolus and the lower third of the fibula. Palpation of the external surface of the leg reveals tenderness. Eversion of the foot produces pain; inversion is restricted by the spasm of the peroneal muscles, and is very painful. Dorsal flexion is limited. An *x-ray* taken immediately shows no bone injuries. This case illustrates a type of injury in which muscles as well as ligaments have been put upon an undue stretch. Along the outer ankle and leg, the skin is hypersensitive, the patient not permitting the palpating fingers to touch the injured area. There is a slight swelling in front and back of the external malleolus.

In this injury, there is a tearing of the external lateral ligament, strain upon the peroneal tendons and their sheaths, the periosteum and the synovial pouch in the back of the external ankle being contused. Three days afterward, when the injured extremity is inspected, there is a considerable discoloration of foot and ankle.

Injuries to Muscular Attachments.—Strains of muscular attachments often give rise to serious impairment of function. These conditions are diagnosed by the fact that there are certain movements which the patient cannot perform because he is suddenly pulled up by pain, which he localizes fairly accurately about some point near the joint. Careful palpation will find a tender spot just at the attachment of a tendon over an area not greater than a half inch, and a little swelling with a suggestion of edema or fluid may be felt deep down on the bone. This spot is the clue to the trouble, and represents either the origin or insertion of the tendon through the periosteum to the bone. The pain and discomfort are due to tension on the effusion by direct pressure or the pull of the muscle. Such an injury may be acute in type, arising from the single twist or wrench of the foot, stretching, tearing or otherwise loosening the strong fibro-tendinous plexus. These cases of tendon strain very frequently become chronic, disabling the patient. The reason why this trivial injury is often so troublesome is because every time tension is put on the muscle, before fibrous union is complete, a fresh trauma occurs in the imperfectly healed tissues, and this repeated time after time maintains the effusion and prevents regeneration of the tendon fibrils.

Diagnosis of Ankle Sprains.—The diagnosis of ankle sprains rests upon, first, a history of the injury; second, the physical findings; third, *x-ray* examination.

All ankle sprains of moderate severity should be *x-rayed*. Very often what is considered a sprain may, on *x-ray* examination, reveal a fracture. A sprain, being a general term applied to all possible injuries that may occur to the soft structures of this joint as a result of a wrench or twist of the

foot, it would be an advance in diagnosis, as well as in applying appropriate treatment, if, through an accurate knowledge, the structures injured could be identified. The x-ray cannot give any idea in this respect. In all subcutaneous traumata, we have to depend upon our knowledge of anatomy in order that we may know what structures are injured. These structures are all hidden from view and we have to feel for tears, and in many instances guess at what has occurred underneath the skin. The x-ray cannot give us a picture of stretched muscle fibers, torn tendon sheaths or lacerated ligaments. It may tell us, however, that there is some distention of the joint. Sprains are diagnosed by the objective physical signs present and the subjective symptoms.

In order that a diagnosis may be made accurately, we must systematically test every movement of the ankle. What influence has movement on the pain? We have to examine every part of the capsule and its various thicknesses for tenderness to pressure and determine where the tenderness is greatest. The same can be applied to the tendons crossing the joint. By an examination in this manner, an accurate diagnosis of the structures injured can be made, and we are then in position to apply the appropriate treatment to these cases.

Chronic Ankle Sprains.—The period of disability of ankle sprains depends upon the severity of the trauma and upon the treatment that was instituted. A neglected or badly treated ankle sprain leads to chronic sprain. A chronic sprain is characterized by pain in the region of the ankle, under either malleoli, swelling and a sense of weakness. Patients tire easily. Chronic sprains, after a time, produce certain bone changes. New facets are ground upon previously healthy bone, and the feet are very often distorted to produce pronation or other deformities. The pain of a chronic ankle sprain is sometimes reflected to the knee, hip and lower back. Very often the muscles, particularly the calf muscles, are in a state of spasm, and the movements of the ankle joint, therefore, are limited in certain directions. If there has been any severe injury to the tendons crossing the ankle joint, sometimes chronic tenosynovitis is set up. This condition is characterized by restricted movements of the joint and pain on walking. If the injury has been greatest in the front of the ankle, the annular ligament, the tendons and their sheaths upon the dorsum of the ankle are indurated. There is tenderness on pressure over the inflamed tendon.

Very often, following chronic ankle sprains, there is an extension of inflammation to the interior of the joint and an arthritis is induced. Adhesions are formed in the joint and in very severe cases ankylosis sometimes follows. In these cases of arthritis, following trauma, it is always well to look for some distant focus of infection, particularly from the genito-urinary tract; gonorrheal arthritis of the foot and ankle being of frequent occurrence.

When the Achilles tendon has been traumatized in a sprain, we may sometimes see inflammation of its sheath or the bursa between it and the os calcis. These patients usually walk in an equinus position and walking is very painful. An examination of these cases reveals a swollen sheath. On each side of the tendon there is an obliteration of the space

normally present in back of the foot. There are areas of chronic inflammatory nodules which appear like shot underneath the palpating fingers. They stand out like a row of beads along the mid-calf and they follow the course of the Achilles tendon, almost up to the popliteal space. These patients cannot dorsi flex their feet because of spasm of this muscle.

Traumatic flat foot is a condition sometimes resulting from injuries to the ankle joint. The arches are depressed and there is pronation deformity. There is often a passive congestion of the foot and leg. The feet are discolored, cold and sweaty. If, in addition, there is added an infectious element, there may be present an arthritis in the joints of the foot. The muscles atrophy. There may be areas of pain and local tenderness at muscular and ligamentous attachment. These patients suffer a great deal of pain and weakness in the feet. Sometimes the muscles are in a state of spasm, the feet assuming a faulty position and being held rigid.

Treatment of Ankle Sprains.—Ankle sprains, being of such common occurrence, treatment, in a great many instances, is inadequate. It is not surprising that one sees cases of chronic ankle sprains in an orthopedic clinic. Lotions, liniments, ointments, tincture of iodine and the like, employed so commonly in these cases, very often prolong disability and jeopardize the future comfort of the patient. These should not be employed in acute injuries to this joint.

The iced compress, lead water and laudanum applications, and elastic compression of the joint are commonly employed in contusions and sprains. These dressings are beneficial in mild injuries. They very often relieve pain, limit inflammation and swelling. Another measure that is useful in these mild injuries is the immersion of the foot and ankle in hot water to which has been added a half pound of magnesium sulphate. These immersions are repeated every three hours. It is surprising how quickly some patients gain relief. The circulation of the joint is improved and the small amount of effusion is rapidly absorbed. Some of these patients are able to go about without any further disability within two or three days.

By far the most effective treatment in all degrees of ankle sprains is immobilization of the joint by either adhesive strapping in the mild cases or plaster of Paris dressing in the severe cases. In this method of treatment, all indications are met. The cure of these injuries is based upon sound physiologic principles.

Concretely stated, one should be guided by the following rules in the treatment of these cases: *First:* Relax the torn or stretched soft structures by reversing the movement followed by the traumatizing force, and immobilize the joint in this position. *Second:* Maintain this position of the ankle until healing of the soft structures has been completed. *Third:* Improve the circulation of the injured part by the use of superheated air, massage and mild, passive movements. *Fourth:* Early functional use, allowance being made that no strain be put upon the newly formed fibrous tissue.

Delayed union, chronic relaxation of ligaments, chronic passive congestion often follow if the above measures be ignored.

Strapping of the Ankle Joint.—Before one attempts to put on adhesive strapping, it must be determined which structures are damaged and the dressing must be applied so as to relax them and maintain apposition of the torn tissues as far as possible. What is essential to the correct application of this dressing is that one have an understanding of the mechanics of the condition for which it is applied, and that each strip of adhesive plaster be applied under tension enough and in such position that it have a real mechanical effect. Thus in case of an injury to the external lateral ligament or its divisions, those are to be relaxed; since adduction and supination is the direction in which the foot was twisted, the foot must be strapped in such a way that it is held in abduction and pronation. It is further important that the foot be strapped more firmly than is apparently necessary, in order that allowance be made for slipping on the skin which always takes place, but particularly when the foot is used to walk or stand.

There are required for a typical dressing seven strips of plaster, four are eighteen inches long and one and a quarter inches wide and three are ten inches long and one inch wide; it is also desirable to include a pad of felt one-quarter inch thick, two inches long and one and one-half inches wide, the latter to be applied in the region of the sprain, to produce pressure upon the local lesion. Instead of a felt pad, several thicknesses of adhesive plaster can be made, the measurement of which being practically the same as the felt pad. Sir Robert Jones advises the use of this adhesive pad with the sticky side out.

Before the adhesive straps are applied, the leg should be cleansed thoroughly and shaved. The foot should be placed at right angles to the leg, and either everted and pronated in cases of external ankle sprain, or supinated and adducted in cases of internal ankle sprain.

To illustrate the application of adhesive strapping, we shall take an injury to the external lateral ligament. The pad of felt or adhesive is first applied to the region traumatized and held there by an assistant. A long strip is then applied to the dorsum of the foot, beginning at the outer margin of the scaphoid and external cuneiform bone and in front of the astragalo-scaphoid joint. It is made to adhere, pulled taut, and passed inward around the inner border of the foot and obliquely across the sole, escaping the tuberosity of the first metatarsal and passed up to the external malleolus. At this point, the adhesive or felt pad is made to adhere to this strip. Being constantly held taut, the strip is now passed upward and slightly inward and made to adhere for the rest of its length over the front of the tibial. A short strip is now taken and its end made to adhere to the base of the first metatarsal, and it should be passed horizontally around the back of the heel and along the outer border of the foot, ending at the articulation of the cuboid with the fifth metatarsal. It should cross the first strip at right angles, just below the tip of the external malleolus. In passing it, this strip should be pulled upon sufficiently to abduct the foot. The second and third long and short strips are now applied so as to overlap the others by one-half. The fourth long strip should begin about three or four inches above the internal malleolus, pass across the sole

of the foot to the external malleolus and vertically upward along the external border of the leg, finally ending a little below the head of the fibula. To complete the dressing, and secure adhesion of the plaster, it is well to apply a bandage to the entire foot and leg, passing this also in such a direction as to secure the desired position of the foot.

This method of applying adhesive straps to the ankle joint is a modification of Gibney's, and, as far as I know, has not been described. The advantages of this method are as follows: A better leverage of the foot is obtained in turning it into the desired position; it is advantageous in injuries to the tendons and ligaments, inasmuch as it follows their course and greater relaxation is obtained, particularly to the peronei muscles.

In sprains of the internal lateral ligament, the direction of applying these adhesive strips is reversed. The modification mentioned above is also advantageous in these sprains because it gives a better support to the calcaneo scaphoid ligaments which are very often injured.

This dressing is removed at the end of three or four days and a new application is made. Walking may be permitted providing the shoe has been properly altered. The alteration of the shoe is accomplished by having the inner or outer side of the heel raised not less than one-quarter of an inch by insertion of leather wedges between the lifts. Sometimes the outer side of the sole may be raised as well by applying a wedge of leather with a space one-eighth to one-sixteenth of an inch. In place of leather wedges, a wedge-shaped piece of piano felt can be inserted into the shoe, so as to raise up the outer border of the foot.

The united effect of the strapping and the wedged heel make it impossible for tension to be put upon the torn ligaments in walking. The physiologic exercises of the foot proves a better stimulation to the normal process of circulation and repair than the best massage, provided no strain is allowed at the seat of injury. In a few days, as a rule, the foot will give no further trouble.

It has been a common observation to see patients who have sprained their ankles wearing soft slippers, rubbers, or things of that kind. This is the worst thing that they can do, because by their use the ankle joint is not supported sufficiently and the young fibrous tissue forming between the ends of the torn ligaments is sure to tear, and then when repair does take place, it is by delayed union. The best shoe to wear in these cases is one with a moderately high upper, tightly laced. The shoe supports the ankle and reinforces the adhesive strapping. I have treated a large number of cases in the above manner and the patients have lost practically little or no time from their work.

In the more severe injuries of the ankle joint, where there has been extensive lacerations of tendons, ligaments, etc., and where the joint has been distended by a bloody effusion, the plaster of Paris dressing is to be employed. If these cases are seen early, the circular plaster of Paris cast is the most appropriate. The foot is placed at right angles to the leg and in a position to relax the torn structures, a preliminary dressing of cotton flannel or cotton batting is applied, reaching from the toe to the tibial tubercle. The plaster should not be too thick. It

is split in the middle so as to allow for separation when swelling ensues. The foot is elevated upon a pillow and the patient is given a sedative for the pain. At the end of five days the cast is removed, the injured part inspected. The ankle joint is lightly massaged and the cast is reapplied. After about a week's retention, passive movements and baking may be instituted. Care must be taken in making these movements that a fresh assault be not made upon the newly formed fibrous tissue. Ankle sprains of this type are very often mistreated by instituting too vigorous massage or movements. At the end of two weeks, the cast is finally removed and the ankle is baked and massaged every day for a week. All the normal movements of the foot should be gone over. Slowly, there is a restoration of function, exudates are absorbed and circulation is improved. If there is some residual weakness in the region of the injured ligament, the ankle may be strapped in the manner indicated above, the shoe being worn and altered as indicated.

If an ankle sprain is seen late, a number of hours after the injury, where there is an extensive extravasation of blood into the joint cavity and swelling of the leg and foot, Stimson's lateral and posterior plaster of Paris splints should be employed. By their use removal is easier, the ankle joint may be inspected more readily and it is not disturbed. Massage may be applied to the exposed parts of the leg and ankle.

The posterior splint extends from the toe along the sole of the foot, around the back of the heel and up the back of the leg to the knee. The lateral splint begins at the external malleolus, passes over the dorsum of the foot to the inner side, under the sole and upward along the outer side of the leg to the same height as the posterior splint. These splints are made in the following manner. A plaster of Paris bandage four inches wide is put into water until it has become thoroughly saturated. The bandage is unrolled upon a table, about six to eight thicknesses are thoroughly rubbed together and the length of which is sufficient to extend from the toes to the bend of the knee; two slabs of plaster of Paris are therefore made. The leg and foot are covered with cotton batting or flannel bandage. The posterior splint is applied first and is held snugly by a gauze bandage to the leg and foot. The lateral splint is applied in the manner indicated and this is also held snugly by a gauze bandage to the leg and foot. During the application of these splints and until the plaster has set, the foot is held by an assistant in a position so as to relax the torn ligament.

This splint is a very efficacious method of immobilization in Potts' fracture, and it certainly is very useful in severe ankle sprains.

After the application of the plaster of Paris splints, the foot is elevated upon a pillow and is kept quiet for three or four days. At the end of this time, the cast may have become loosened owing to reduction of swelling. Light massage is instituted and the foot is moved once only in all directions. We can then either reapply this dressing or can apply a circular cast, the latter being a more stable form of dressing.

In the treatment of strains of muscular attachments, our object should be to get rid of the effusion

which separates the torn ends of tissues and so allow them to come into their proper position. Our object should also be to prevent any movement of muscular effort from stretching or tearing the newly repaired tissues and so making the condition chronic. This is done by applying a pad of adhesive plaster over the effusion and a similar pad upon the tendon, just above the inflamed area, a bandage being applied over these. In chronic strains of this kind, treatment must be directed in encouraging a free flow of blood to and through this area. This is accomplished by massage and alternating applications of hot and cold water (contrast baths).

In the treatment of chronic ankle sprains, where the foot has assumed positions of deformity, it is sometimes necessary to give an anesthetic, manipulate and break up adhesions, tenotomize contracted tendons, and bring the foot around to its normal relation to the leg. The foot is fixed in the correct position in a plaster of Paris cast. After a period of two or three weeks, the cast is removed and a light brace to restrain lateral movements is temporarily applied or a pair of shoes are wedged and furnished with arch supports. These cases should be baked and manipulated regularly for a time if they show any evidence of arthritis. All foci of infection in distant parts of the body must be searched for and treated.

1811 SOUTH BROAD STREET.

A CONCEPT OF X-RAY PATHOLOGY.

I. INTRODUCTORY.

By A. J. PACINI, M.D.,

WASHINGTON, D. C.

CHIEF OF LABORATORY AND X-RAY SECTION, HOSPITAL DIVISION,
U. S. PUBLIC HEALTH SERVICE.

IN theory, there is no substance impenetrable to the x-ray. It should be possible theoretically to permeate whatever substance provided that we can control the intensity of x-ray generation.

In practice, the field of x-ray physics is limited by the mechanical perfection of the instruments available; so that there is a limit to the class of substances that we are able to penetrate or unable to penetrate with the x-ray. The essential pith of the situation is this: that penetration is a relative term. It depends upon two factors; the physical electrical intensity of the generated ray, and the atomic-density of the material to be rayed.

Ottolengui introduced the terminology radiopaque, radiolucent, radioparent. Radiopaque is coined to mean the condition of exhibiting opacity or impenetrability to the x-ray; radioparent is coined to mean transparent, or penetrable by the x-ray; and radiolucent is coined from translucent and means moderately penetrable, or moderately impenetrable by x-ray. Now, how manifestly it appears that the terms radioparent, radiolucent, and radiopaque are entirely relative. For example, in exposing a hand to the x-ray, it is possible so to regulate the factors of x-ray exposures that the bony framework will remain radiopaque, the fleshy parts radiolucent. By increasing the voltage or spark gap of the x-ray supply, the fleshy radiolucent parts become radioparent, and the bony radiopaque parts become radiolucent. It is possible to increase the spark gap and exposure to an extent that even the bony frame-

work will become radioparent. Fundamentally essential then is the primary concept that, applied to x -ray anatomy, histologic structures bear to each other certain relative values of atomic density. The atomic density of the histologic unit determines the relative radiability of the anatomical part. Relative radiability is the determinant of x -ray pathology.

FACTORS AFFECTING RADIABILITY.—Since radiability is the determinant in interpreting x -ray pathology, it is necessary to analyze the manner in which radiability may be affected. Two factors affect the radiability of a part. First, the normality of the histologic structure may be only moderately modified as to architecture; but its individual units, through various processes of pathology, may acquire a supernatural density and become, thereby, relatively more radiopaque. As an example, the parenchyma of the lung appears radioparent, or at most radiolucent, on an x -ray plate taken with the usually accepted standards of x -ray exposure. When, as the result of irritation the parenchyma undergoes connective-tissue proliferation, it acquires an increased atomic density sufficient to cast an x -ray shadow. The general orientation of the parenchymal framework is barely altered; but the chronic interstitial pneumonitis that makes for increased atomic density of a parenchyma, makes radiopaque the previously radioparent structure. So that, the significant x -ray pathology of chronic interstitial pneumonitis can be reduced essentially to a disturbance of the relative radiability of lung structures; and what formerly was radioparent has, by pathology, become relatively radiopaque.

Increased Radiability.—Some structures, such as the alveolodental membrane, when invaded by a purulent attack are so altered as to become increased radiable. Under usual technology, and in normal condition, the alveolodental membrane appears radiolucent; but the effect of early purulent inflammation reacts so that this already soft tissue becomes even softer, and, owing to the loss of atomic density, becomes radioparent.

Pathology may react, then, simply on the structure of a tissue so as to produce increased radiability, or so as to produce decreased radiability. Under these circumstances, the normal structure remains practically unchanged in form, and only the relative radiability of the unit is affected. Obviously, the x -ray interpreter must learn x -ray histology not in terms of absolute x -ray architecture, but in terms of relative atomic density of the constituent histologic units that comprise a viscus. In terms of shadows, the x -rayist must master the fact that large blood vessels, for example, are relatively radiolucent compared to small blood vessels; and abandon the erroneous conception now prevalent that large blood vessels cast shadows and small blood vessels fail to cast shadows.

Relative Radiability.—Conceived in the vision of relative radiopacity, the x -ray interpreter suspects pathologic changes when the x -ray plate reveals small vessels that are radiopaque; for, having established that when large vessels are radiopaque, small ones normally should be radiolucent or radioparent, abnormality must exist if conditions are such as to cause small vessels to be equally radiopaque as large vessels.

Normal Relativity.—With this criterion, the cri-

terion of normal relativity, our conception of the normal plate becomes better standardized; for, under this category, a plate is normal when the various histologic structures that comprise its anatomy are revealed in their relative intensity free from anatomic deviation. X -ray pathology begins, paradoxical as it may seem, with the study of the x -ray projection of normal structures.

GROSS HISTOLOGY AS A BASIS FOR X -RAY PATHOLOGY.—Homes and Ruggles present several axioms as bases for successful Roentgen interpretation. One of these axioms reads, "be familiar with the projected appearance of normal structures." The axiom is basic in essence. It needs only to be amplified in regard to the adjective "familiar." Familiarity with the projection of normal structures should include a minute intimacy with the projection of the very histologic units that compose a tissue. Of course, the individual cells of a tissue are not projected; but anatomic detail is not sufficiently exiguous. The phrase, "gross histology," would seem to convey the thought indicated. Not cellular analysis of shadow, for individual cells are not revealed; not anatomic outlines of visceral projection, for this is too crass; but an intermediate phase between cell minutia and visceral hugeness—gross histology.

ANALYSIS OF X -RAY MODULANTS IN PATHOLOGY.—Under the heading of Factors Affecting Radiability, it was outlined that the architectural structure may remain virtually unchanged; that the atomic density, which affects the radiability of the part, may suffer increment or decrement. Thus, certain pathologic invasions are revealed only by the relative variations in radiopacity. Radiopaque variations include those reflected by incipient inflammatory changes; by characteristic interstitial affections; or, in general, pathology involving actual increase of atomic density as the result of an influx of fluid (*i.e.* blood stasis and vascular engorgement in early inflammatory dramas) or occasioning an atomic density increment in a tissue as the result of chronic proliferative pathology.

Then there is a second modulant. A tissue normally radioparent, or radiolucent, may become the seat of an infiltration. The infiltrate may be a radiopaque pathologic product; and, without affecting the radiability of the pristine tissue, the injected radiopaque product causes a shadow. Muscular tissue, usually, is radiolucent; but in myositis ossificans, a calcareous infiltrate is showered into the muscle bundles and that muscular region becomes radiopaque.

It is readily detectable whether a shadow results from decreased radiability of a tissue or from a superadded radiopaque injection; in the first case, the histologic unity of the shadow is recognized; in the second case, the obliterated histology incident to the superimposed agent causing radiopacity is clearly discernible. Thus, in pneumonia, the characteristically triangular shadow of hepatization is immediately identified as a modulant not affecting histologic structure, but more as a superaddition of extraneous material.

The third modulant results from a process converse to that responsible for the second modulant. Instead of the superaddition of material to an area, there may be occasioned an absence of tissue that

should normally occupy that area. The most brilliant example of this modulant is the case in pneumothorax. Here, the normal shadow of pulmonary network is missing from the thoracic field involved, and a homogeneous radiopacity, free from structure, asserts the absence of gross histologic groupings.

Finally, perfectly obvious and well understood variations may be noticed, such as marked adenopathy of the root glands at the lung hilus. Hypertrophy, atrophy, hyperplasia, and aplasia are clearly matters of size, in x-ray pathology, so that the last modulant is that of the size of the part.

All pathology invading the human body, if it produces registrable x-ray evidence, that evidence will be manifested as a variant from the normal according to one, two, three, or all four of the x-ray modulants: (1) Changes in radiopacity without great change in structure; (2) obliteration of gross histology by superadded material; (3) elimination of gross histology by tissue displacement; and (4) changes in the relative size of a histologic group.

Orientation of Modulants.—If the circulation in the lung is studied, it is found that the periphery of the organ is supplied with a slower and somewhat different vascular system than the remainder of the viscus. In this relatively inactive circulation involving the margin of the lung, the tubercle bacillus finds conditions for establishing growth less fraught with adversity than in the more active central circulation. Thus, capillary engorgement in the pulmonary medulla may be due to whatever infectious respiratory organism; but similar engorgement in the periphery, following the law of probability, would suggest a particular infection—tuberculosis.

The situation is this, that the same character of relative change in radiability induced by pathology that one secures in a certain location has an entirely different value in some other region of the same viscus. So that the orientation of the modulant must be studied in the light of the reaction of the normal physiology against the pathological invasion.

Intensity of Modulant.—A deciding determinant is often the intensity of the modulant. In a muscle, for example, sarcomatous infiltration will make for a shadow of different intensity from that caused by the lime accompanying a myositis ossificans. The hard nodule of a carcinomatous metastasis in the lung would naturally be expected to cast a denser shadow than the soft diffuent shadow incident to a locus of circumscribed pneumonia.

BIOLOGIC SYMMETRY.—The animal differs in one respect from the highly organized plant in that the animal offers a symmetrical organization. Animal symmetry is not absolute. Thus while there are two lungs, the pulmonary fields are not exactly identical; they are similar, but have certain anatomic variations characteristic for each lung. The similarity of symmetry is sufficient, however, to refer an abnormal marking on one side for comparison to the normal marking on the other side. More important than the symmetrical comparison is the absolute comparison. That is, comparing the abnormal markings in one lung with the normal markings in the same lung.

SUMMARY OF CONCEPT.—Whenever pathology pro-

duces a change that involves sufficient variation in the atomic density of the invaded structure, that structure will suffer an alteration in its relative radiability. X-ray pathology means the study of x-ray modulants interpreted in the light of the pathology responsible for relative changes in radiopacity, for relative distribution of the shadows, for the density of the shadows, all compared to the relative normal. The normal is not an absolute standard; nor is it necessary that it should be. It is a standard whereby a knowledge of the gross histology of the part determines in the mind of the observer the relative radiability of the structures.

With this concept of x-ray pathology, uncertainty is eliminated and x-ray interpretation is placed on a basis of anatomy, gross histology, physiology, and pathology. How these factors are blended in the setting of the clinical study of the various disease entities with which the roentgenologist copes will be subsequently discussed for each group of organs, for each type of pathology.

THE LOGICAL CAUSE, PATHOLOGY, AND TREATMENT OF BRAIN LESIONS. AN EXPERIMENTAL PAPER.*

By ALFRED KAHN, M.D.,

NEW YORK.

AT different times, over a period of a number of years, the thought has repeatedly come to my mind in thinking of brain lesions from otological origin—why it is that many of these cases die either where they have had operative treatment or where nothing of a surgical procedure has taken place, and why it is that many of these cases recover, even where no therapeutic defense is brought into play. This latter class of cases of brain involvement just simply recover. Cases of brain abscesses have repeatedly been diagnosed as brain abscess only on the operating table. Their presence was in many cases not even suspected. Brain abscesses have been found on the post mortem table, where the patients have come to their end through some other intercurrent condition. Brain abscess cavities have been found to be filled with a purulent substance walled off—this purulent substance was found to be bacteriologically sterile. Can it be doubted that at some previous time this purulent appearing substance was infectious and of pyogenic origin?

It has often seemed to me—and I have repeated it here at various times, in discussion—that our surgical principles as practised were not surgically logical; that our procedures, although the best we had at hand, were inadequate, that we often, for example, opened the subdural space and did a decompression operation, that we often explored for brain abscesses where no brain abscesses were found, that we did these things surely because we thought them advisable, and largely because they were the only means that we knew for combating these complications. Do not misunderstand me—I know that we have arrived at these procedures through years of development, clinically, surgically and experimentally, and I have great respect

*Read at a meeting of the Otological Section of the New York Academy of Medicine, May 14, 1920.

for these procedures. It is only with an intense desire to give something, to do something that will perhaps precede or go hand in hand with this knowledge which we have so laboriously accumulated, that I have interested myself in the matter.

This subject is an extremely difficult and broad one, and in this comparatively short paper I am trying to group a variety of different complications—I mean brain complications of otological origin. This, in substance, chiefly refers to infectious meningitis and brain abscesses.

Among the first questions which arose in this experimental work was what is meningitis—what is brain abscess—how do they occur—what is the pathology of these lesions? Briefly stated, I concluded that meningitis, brain abscess—were the result of infections by a pyogenic germ or germs—and these experiments will endeavor logically to show that—first, let us say for example, in meningitis, the germ attack is made at some particular spot of the meninges, that the point of attack is more intense (that the irritation is more intense—that the reaction is more intense) at some one point on the surface of the meninges than at any other point. Logically, there must be a spot of beginning. This is the point of invasion, this is where the battle starts. The system, either immediately or after a period of time (an incalculable space of time, an infinite space of time) reacts according to its ability, and you have a state of inflammation, a state of congestion, exudation, and transudation and absorption. And now your clinical symptoms start (fever), a change in temperature, either first a rise or fall. This may not be noted in the clinical chart; this is followed almost invariably by a rise in temperature and you have your clinical vibrations—the character of the blood begins to change—change in number of leucocytes, quantity of blood, consistency of blood, presence of antitoxin and immune bodies—at first gradually, then in increasing amounts, finally the presence of toxins, then germs in the blood—at first dead, finally as death nears, living germs.

These clinical symptoms and signs and reactions on the part of the system you all are acquainted with, but what I want to especially point out is that you have two processes taking place in an infection of this character. That you have first a local process, an inflammation at the point of invasion, that the system at this point of infection is continually trying to localize, to surround the point of irritation. When a patient recovers, what in reality takes place—the point of infection is localized and absorbed, or it may be only localized without absorption, and you have your brain abscess, for example. Now this brain abscess may remain infectious, quiescent, or the sting may be taken out of the infectious substance by the immune activities of the system, and you have your sterile pus cavity. I do not believe this latter class to be dangerous. In addition to this localized point, the debris absorbed from the point of battle is taken up into the system and you have your toxemia, and the system forms antitoxins and throws out immune bodies, and inaugurates other means of defense. Now, if the defensive measures inaugurated by the system are strong

enough to overcome the activity of the invading organisms, your patient recovers. If the activities of the invading germs are overwhelming, your patient dies. Now what I want to particularly point out and especially call your attention to, is that the patient does not die from the local process, unless of course, the localized area should cause pressure on vital centers—but that the patient dies from the absorption of poisonous toxins from the localized area of battle. This you might dispute, but I will show you through a series of experiments performed within the peritoneal cavity on the peritoneum, where there are no vital centers to be pressed upon, that the same thing takes place and that the patient does not die from the local spot, but that the main thing is the poisoning of the system through absorption. Now you must see that this could not logically be otherwise, and you must therefore also see that our final great success in treating these complications must come through the general system, more so perhaps than at the point of local invasion.

I will not take up your time unnecessarily by enumerating each experiment separately, and going into the detail of each experiment. These experiments were carried on in the laboratory of Experimental Surgery, New York University, and the conclusions arrived at may have been the result of one experiment or they may have been the results of experiments on several dogs, or finally it is the impression made upon my mind, drawn from these conclusions at this writing. First, I learned that absorption from the sub-dural space is quicker than in the peritoneal cavity—that in operations upon the brain the element of shock is very much greater than in operations in the peritoneal cavity, that reactions upon the part of the system to infections within the brain are slower in comparison to infections in the peritoneum, but absorption is quicker. My primary object in doing these experiments was to learn first if I could infect a dog and allow him to go to a point where death from infection seemed imminent, and then to see if I could not bring into play some force that would keep the dog from dying. I first opened the peritoneal cavity of the dog, and took dust from the laboratory room and placed it in the dog's peritoneal cavity. Where dust was used in this way the dog practically invariably recovered without any interference on my part. The germs streptococcus and staphylococcus from the laboratory (I call your attention especially to the fact that I mention laboratory germs) were injected into the peritoneal cavity and into the blood stream of dogs and nothing happened. I took small pledgets of gauze saturated with pus taken from dogs that had just previously died from a purulent infection. I then took pure pus without being saturated with gauze (liquid pus) and put it in the peritoneal cavity. This liquid pus was taken from dogs that had just previously died from a purulent infection. Where the pus alone was used, the dogs became immediately very sick and many of them died within twenty-four hours. Post mortem: In many instances showed no reaction whatever. In other instances where pure pus was used, there was evidently an endeavor on the part of the system to react and

throw up a defense, for the peritoneal cavity was intensely inflamed and purulent. When gauze saturated with dust from the room was used, the systemic reaction was very slow, the dog would recover, and on post mortem, would show the gauze walled off. Where gauze saturated with pus was used, the reaction was more intense and quicker than where gauze saturated with dust was used. These dogs became quite sick, but some of them recovered and on post mortem in this class the gauze would be either entirely walled off or the walling off would be very far advanced; that is, if the dog had recovered, and the post mortem done some days later, the gauze would be entirely walled off, but in those dogs that only lived a few days, after the original infection, the gauze would be in various stages of being walled. Where pure pus was used, the peritoneal reaction was not comparatively as great nor did the tissues to the naked eye seem to localize at all. Of course, the previous experiments had a foreign body, which acted as both an irritant and a nucleus around which to localize, but in those cases where pure pus was used, the systemic reaction took place almost immediately, and these were the hardest cases to handle, as very often the dogs would die from toxemia before any treatment could be started. The practical conclusions to be drawn from these experiments are as follows. First, that it is not the infectious organisms by themselves alone or dirty material containing these germs, of a non-animal character, that is so dangerous, but what really causes the toxemia and final death in these cases of peritonitis, meningitis, brain abscess, etc., is the absorption of the debris resulting from the strife of the tissues on the one hand and the invasion of the infectious organisms on the other. Secondly, that clinically speaking, the more important process is the systemic toxemia. This is what causes the final death. It is not the local process, for the local process is finally, if at all, overcome by systemic activity. Thirdly, that any serum treatment to be found in the future will owe its success or failure to overcoming the debris resulting from this infectio-inflammatory combat, and that it will not be based upon the activity of germ life in the laboratory. In other words, it will probably be an autogenous serum. Before proceeding further, I overlooked stating that we injected directly into the blood vessels of some of these animals weak solutions of citrate of soda and blood that were not sterilized—solutions that were surely filled with all forms of bacteria—and that the animals were not in the least affected.

By way of remark, it may not be out of place to draw further conclusions from these experiments. It must be remembered that when we introduce pure pus into the peritoneal cavity, or into the sub-dural space, pus from another being is not the same thing as pus being formed in a subject himself—it is a more toxic test. In the latter case, before pus is formed, the system has gone through the various stages of irritation, inflammation, localization, breaking down and absorption, absorption only taking place when the pus is formed. In the first case, however, the economy does not go through all of these various stages, but pus is introduced directly as pus, with-

out having been manufactured at any point of localization. Therefore, the body has had no chance to react and no chance to form antitoxins. Absorption takes place directly and your patient is poisoned before antitoxin can be formed. And this absorption took place so quickly from the sub-dural space, that the few dogs upon which I tried it, died before I could do anything with them. The absorption from the peritoneal cavity is slower and the system has some chance to form antitoxin and attempt to immunize itself. These conclusions may not be absolutely correct, but it is the only way I have been able to interpret them.

Treatment.—The next question that now arises is how do you propose to cure such a state of affairs. The procedures now used are practically all surgical and are applied to the local lesion, and they consist in cases of meningitis, primarily of decompression; this is done chiefly to give the brain tissues more room to expand; it doubtless has value in this regard. As to the value of an early or late decompression, I do not think that we are at all sure. To my mind, in one instance, a decompression may be of value; in another instance, it may be of little value, or of no value at all. I believe that our success in treating these cases in the future will develop along lines that have a tendency to immunize the system to the invading organisms until the cells in the localizing area are able to localize the infection, and I can only see two possible ways of meeting success. Although it is not intended to cover the first in this paper, I think it should be mentioned. I believe that it may be possible to make a serum that will be effective. The germs entering into the formation of this serum will have to be propagated and fed on human blood or human tissue. In cases where meningeal or brain tissue is involved, if the germs entering into the formation of a given serum could be fed on brain tissue or meningeal tissue, or upon the blood of the patient himself, I think the serum offers a chance of success. I do not believe that germs cultivated on any other artificial media will have a chance to succeed. The second method is covered by this paper, and I believe offers our first immediate chance of success. And this method is a method of transfusing blood from one person to another and back again, over a period of time or at frequent intervals, and is a method which I described nearly ten years ago, and which is covered by these experiments, as follows: At the start I want to state, so that there will be no misunderstanding, that this method has never been tried on human beings. The work following is purely experimental on animals, but the success of these experiments has been of such a nature that I believe it would be perfectly safe on human beings.

My experiments consisted of infecting the peritoneal cavity of dogs in the various ways that I have mentioned before. The dogs were infected with pus from other animals, which had previously died of the purulent infection in question. I soon learned that within twenty-four to forty-eight hours a dog would reach the height of his infection, and if he were not transfused in the way in which I have described before this elapsed time, that he would die; that those dogs that were transfused within a period of twenty-four to forty-eight

hours either made a total recovery or they lived several days longer than those dogs which were not so transfused. That when the peritoneal cavity was infected as described, the dogs transfused according to this method would almost invariably recover, but when they were not transfused, they would die within a period of forty-eight hours to several days. The technique of these experiments was as follows: On the first day the dog's peritoneal cavity would be opened and the infectious material inserted. After an interval of twenty-four to forty-eight hours, depending on the nature of the infectious substance, but chiefly on the condition of the dog, he would be transfused. The transfusion in several instances was continued for a period of from thirty minutes to two hours, a continuous circulation of blood between the two animals.

The next question is apt to be, what takes place when the circulation of blood is continued between the two animals? I have already shown you during the state we clinically call meningitis, that there is a battle for existence and that there is an absorption of toxins, and there is a manufacturing of antitoxin—and the system is trying to immunize itself. Now, let us say, that the toxins have the best of it; that the system is loaded with toxins. Now if you can take away part of these toxins you are reducing the poisonous dose just so much. When you transfuse in the way I suggest, this poisonous blood passes over to another animal, and if the transfusion is continued, it reduces the poison in the infected animal just one-half, because it must be remembered that while this toxic blood is passing over to the healthy animal, an equal quantity of healthy blood is passing over to the diseased animal, in each instance, having been reduced one-half, and the toxin kept below the point of a poisonous dose. At the same time it must be remembered that the blood from the diseased animal to the healthy animal contains substances which will cause the healthy animal's organs to act and react and form an additional amount of immunizing substances, thereby increasing the force of resistance, let us say, perhaps another 50 per cent. The diseased animal is reinforced with an equal quantity of healthy blood, blood which is further capable of manufacturing immune substances, thereby increasing the diseased animal's chances still more. If the diseased animal, after a lapse of twenty-four to forty-eight hours, is again transfused with the same healthy animal, his blood is still further reinforced by antitoxins. This can be repeatedly kept up until the local point of infection is walled off and the diseased animal able to take care of himself. In other words, by frequently repeating the transfusion the diseased animal is put into an antitoxic state, following an exact example set by nature, and he is finally absolutely cured. Now, what takes place in the healthy animal? We are not injecting pus from the diseased animal to the healthy animal—you are injecting a substance called toxins, if you will, but of a dose insufficient to kill. You are not necessarily injecting infectious organisms, and even if you were injecting free organisms, the organisms without the débris are not so apt to affect the healthy animal as you

may imagine. The débris—as I have pointed out to you—is the substance which kills, and that is represented by the toxemia. In this connection, I wish to state that I did not lose a single donor from infection. The healthy dog never developed an alarming toxemia, and none of them died from infection. Another question that may arise is, why wouldn't saline solution or a direct transfusion of blood—why wouldn't these two methods be just as good as the continuous transfusion method that you advocate? I believe that both of these methods have some value in this connection, but I do not think it is very great, for this reason: If saline solution were injected into the blood stream in any quantity, it is true that it would dilute the toxins, but it is also true that it will reduce the antitoxins also. The relative quantity of toxins still remains, and the relative quantity is what kills. It is also a question as to whether saline solution by its stimulating effect, would not cause faster absorption. Now, as to the direct transfusion of blood, to a certain extent the same thing takes place as takes place with salt solution. Both the toxins and the antitoxins are diluted, but even if the antitoxins were not diluted, do you think you could introduce a sufficient amount of blood to really amount to anything? The relative quantity of toxins remains; and then you cannot dilute the vessels to the bursting point, or you are apt to have cerebral hemorrhage, or an engorged heart; so in the last analysis, you can readily appreciate that the method I describe is the only one, up to this writing, which offers any chance at all. The diseased toxic blood is removed and replaced by healthy blood, quantity for quantity, by a method which can be continued for an almost indefinite period without loss of a drop of blood—one more than the other—if necessary, to either animal.

50 EAST FORTY-SECOND STREET.

PSYCHIATRY AND PSYCHOANALYSIS.*

BY JOSEPH SMITH, M.D.,
BROOKLYN, N. Y.

PSYCHIATRIST FREE SYNAGOGUE MENTAL HYGIENE CLINIC, NEUROLOGIST O. P. D. JEWISH HOSPITAL, BROOKLYN. FORMERLY SENIOR PHYSICIAN BROOKLYN STATE HOSPITAL.

THE most intensely interesting problem for the psychiatrist now-a-days concerns the fundamental conceptions of dementia præcox. Much speculative thought has been directed toward the elucidation of this problem. In his psychology of dementia præcox Jung attempted to explain psychologically the origin and mechanism of certain symptoms and traits of dementia præcox and there seems little doubt that Adolph Meyer was moved to the formulation of his conception of dementia præcox as a habit deterioration by some of the conclusions to which Jung arrived in his well-known book. I may point out, for example, Jung's explanation of the deterioration of the utterances in his patient—how a word or phrase may through symbolic or other strained connection become so changed that it loses its original meaning and may even become incomprehensible. Meyer, following this reasoning, has announced his theory by gen-

* Paper read May 25, 1920, before the New York Psychoanalytical Society.

eralizing this conception: Dementia præcox has become now a habit deterioration.

This leads me to say a few words concerning the generalizing process itself. The mind can readily leap from one idea to another without apparently any connecting link, the slightest similarity being sufficient to connect two facts. I always felt that some of the associations which Freud used were so far stressed that their connection can be appreciated only by himself and then in a dim way, by a sort of intuition. In the same way the apparently incongruous connection between dementia præcox and neurosis has been made into a congruity between the two. All you need to do this, is a rich phantasy or imagination. It is possible for one gifted with imagination to construct any tenable hypothesis. We meet with many illustrations of this linking which lead to far-reaching generalizations. The notion of the brotherhood of man, for instance, may have had such origin. Psychoanalysis offers a rich field for generalizations of this character. Nobody will dispute the fruitfulness of this generalizing process—the story of the falling apple and Newton's discovery of gravitation is just such an instance of the far-reaching consequences of fertile imagination. But here also lies the danger—the eradication of all differences of shades and varieties. To avoid this, one should never lose sight of the fact that this tendency to generalization is an inherent faculty of our mental life, a yearning after oneness in the welter of universal phenomena, and that similarities observed in other mental processes may partake of the same desire to bring under one caption phenomena of an apparently heterogeneous order. Not only in metaphysics but in science do we observe this tendency to unification. Herbert Spencer observes that he who has recently become aware of a fact is apt to overemphasize that fact. One who has recently become lame discovers how many lame persons there are in this world. This is an important truth.

One may ask, "What bearing has all this on psychoanalysis?" Only this, that observation having led to the formulation of a certain conception of the etiology of neurosis has resulted in the generalization of this conception until it is hotly denied by some that there may even be a possibility of other etiological factors. The danger here is that it may lead to dogmatic assertion. All depends upon the manner in which we approach a problem, upon our mental attitude. Let a certain fact strike you with sufficient force and you are overpowered, and it becomes well-nigh impossible for one not to become partial to it. An extreme development of this tendency to oneness begets intolerance and bigotry. In the light of these considerations, the truth of which will probably not be disputed, it will be possible better to evaluate certain of our conceptions and generalizations.

The extent which this *Drang nach Veralgemeinerung* may assume may be seen from the inclusion of epilepsy, psychosis, etc., among those diseases which have as etiology mental factors. This results in a wiping out of all differences until no clear-cut etiological or clinical entity can possibly be said to exist. The practical consequence of such a frame of mind is that in the State Hospitals, for instance, there have existed doubts almost as to the fundamentals of a psychosis. If a given psychosis may

be a dementia præcox, a manic-depressive, a hysteria, or an epilepsy, the result is a hesitancy to call it anything definite. This reached at one time such a state of doubt that the slogan was: "Never mind the diagnosis, study your symptoms, describe what you observe, get the facts," etc. This doubt I think can be traced directly to this generalizing tendency, which gets hold of us every time a great theory is being propounded.

About a year ago I had a patient, a boy of fourteen, under observation at the hospital; the boy was bright, intelligent, attended high school. There is considerable of the neurotic make-up in the family. The boy used to help out in the laundry a few hours a day after school. One day he suddenly got excited, spilled ink on clean linen, raised a club against his employer who scolded him, and a policeman had to take him home; there he was quiet for a while, but soon became disturbed, threw pillows about the room, and was finally hurried to the hospital. When admitted he was very talkative, interfering, protested his innocence; he remembered all the incidents which led to his commitment. At first the condition looked very much like a manic upset—the restlessness, talkativeness, rapid onset. A few days after admission I was informed by an attendant that the patient had a weak spell, he sat in the chair and suddenly became limp and slid down to the floor. My suspicions were aroused. The patient rapidly improved, however, and as the people were very anxious to have him home, he was paroled. He appeared at the hospital several times, looking well. One day he suddenly became disturbed and began to throw things about the rooms and was hurriedly brought back to the hospital. Here he seemed somewhat confused, but soon came to himself, began to talk excitedly, and later, I was informed, he defecated and smeared his hands with fecal matter. Closely questioning his sister, I obtained from her the statement that on two occasions when he had been in the car with her he seemed to become suddenly mute, absentminded, had to be "roused," and once he emptied his bladder on such an occasion. I immediately told her her brother suffered from epilepsy. After a few days the boy was paroled home. I advised his sister, a school teacher, to take the patient to a known neurologist and have sent a full report of the case to the doctor. He examined the boy and declared him not an epileptic. I lost track of the case for nearly a year, but lately was visited by his sister, who told me he has major epileptic seizures now, and she asked for my assistance to place her brother in an institution.

What I wish to emphasize here is not my sagacity or the other doctor's shortsightedness, but to point out wherein the mistaken diagnosis may lie. Having his mind directed toward certain psychic aspects in epilepsy, the doctor was loath to call that epilepsy which did not behave according to a preconceived formula. Here it may be interjected: We study the phenomena as they present themselves to us, clinical observation of a great number of cases has furnished us with certain facts and it is quite logical to deduce general principles from the observed facts. I must admit that the case is put strongly. In answer to this let me say that we are not so much concerned here with facts as with the inter-

pretation of facts, and this depends upon our own individual preferences, our likes or dislikes. James said that our philosophy of life will depend upon whether we are constitutionally tough-minded or tender-minded, and I believe that our interpretation of facts in psychiatric and psychoanalytic fields will depend a great deal upon something very similar to this make-up in our constitution. I have gone at some length discussing this somewhat threadbare and trite theme and I am sure some of you may be wondering what it is all about. I must say that such thoughts have occupied my mind from time to time. In reading a psychoanalytic interpretation of some dreams or of cases of dementia præcox the thought frequently popped up in my mind—one always finds what he is looking for, in other words, one reads into the case, unconsciously of course, a great deal of one's own preconceptions. Practical psychoanalysis at best is only a crude way of estimating ideation—a great deal is left to individual interpretation. The mind's work is too fleeting, ideation too rapid, and the associative links in the chain of ideation invisible. How is it possible by crude methods to trace back that which the mind itself is incapable of registering adequately and consciously? Subconscious processes are too fleeting and tenuous for conscious operations to retrace their steps.

During the past few years I have seen a large number of cases in connection with mental hygiene clinics. These clinics offer no facilities for psychoanalytic investigations and only a superficial estimate of the condition, and conflicts of the individual is possible. A great number of the patients were foreign born, often past thirty-five, lacking in the intelligence requisite for psychoanalysis. They all suffered from some form of neurosis; the neurotic character of their complaint was sufficiently evident and yet I was impressed by the absence of sexual thoughts or fancies as relating to the complaint, and I was forced to conclude that a great number of these nervous symptoms were attributable to economic factors, others to exhaustion—steady toil, routine, and monotonous occupations, deprivations, large families, and the consequent struggle to maintain them, etc. It may be objected to that since no psychoanalysis was attempted it is not justifiable to conclude that there were no upsetting sexual factors. I believe, however, that in nearly all cases we are conscious of a feeling in the presence of the patient that he has some conflict or other. *Psychoanalysis only amplifies and determines the particular details of the upsetting factors in a neurosis.*

We will now return to the consideration of the dementia præcox problem. It seems to me unthinkable that dementia præcox should be simply a further development of arrested or perverted instincts and habits. The formation of bad habits will never lead to disintegration of personality, to such loosening of concepts, such delusional formation as we see in this disease. There is a wide gulf separating paraphrenia and dementia præcox. Your paraphrenic is a queer, odd fellow; he may have some particular hobbies but he preserves a certain contact with the world. To an extent, he can be beneficially influenced, arguments may lead him to change his way of thinking. When this result cannot be obtained, it is due to that tendency which

acquired habits and thoughts have fostered, namely, a stubborn resistance to any attack on these habits and thoughts. The paraphrenic can no more give up his mode of action or thought than a standpat Democrat or Republican can change his political views. He has reached a stage where it is comfortable for him to exist without outside interference. Not so the præcox, whose condition goes from bad to worse, the final outcome of which is complete stagnation or perversion of mental life. I believe that Bleuler, who is the clearest psychiatrist of them all, has erred in his extension of the conception of dementia præcox by including so many allied but different elements in order to comprehend all under his term of Schizophrenia. If we keep in mind that dementia præcox is essentially a juvenile chronic disease leading to progressive deterioration, we will circumscribe it far better and keep out various other groups that should be kept apart and studied independently, often more is to be gained by exclusion than inclusion. For example, we may allude to the separation of a clinical entity—anxiety-neurosis—from other forms of neurosis by Freud, which led him to enunciate a somewhat different etiology for this group of cases. There is no doubt that psychoanalysis has gained by this conception.

What can be said about psychoanalysis in dementia præcox and allied condition? If we keep in mind that psychoanalysis is a method of bringing to light and before reason conflicts which oppress the individual, and that the practical solution of the trouble depends upon the retention of the powers of reasoning in the patient, it will at once become clear that where reasoning is affected, no such favorable results can be looked for. For the neurotic does not suffer from loss of power of reasoning, but from either subconscious or conscious conflicts. In the first instance, it is of course plain that the ideas must first become conscious before they can be dealt with logically. In the second case they are so laden with affect that reasoning proper is interfered with. In the dementia præcox, however, reasoning is primarily affected—and here I fully subscribe to the doctrine of Bleuler—hence no results are to be expected from psychoanalysis. Psychoanalysis will not favorably influence the deterioration of habits or instincts since they themselves are to be regarded as symptoms of the disease and not a cause of it. Psychoanalysis is also not essential; you do not have to analyze a woman who tells you at the first interview that she hears voices slandering her character, calling her an immoral woman, etc.

A girl of twenty-seven, whose sister is at King's Park, New York, had been in a nervous state six months before she came to the dispensary. She was tormented by voices. People would say, "What and look." She would hear a word signifying coitus. Sometimes she was pleased to hear the voices. Sexual thoughts occupied her mind. She said, "When I was ten years old I did it with a boy, and now it is on my mind constantly. I fear I am going insane." She constantly murmured, "Jesus, save me." There were some somatic complaints, pains in the left temporo-occipital region, behind the ear, in the head, flashes, creeping sensations, oppression. For months she had been coming to the clinic, invariably complaining of the voices and sexual thoughts. She could not bear the mention of marriage, sexual relations, or the word miscarriage. She displayed agitation and uneasiness, prayed frequently, cried, thinking she was blaspheming God. When she

was washing the windows she was insulting Jesus; when she looked at the crucifix she imagined she stepped on it. She feared something would happen to her on the street, she might fall into the hands of strangers, etc. All this she told openly, freely, without my asking her; she was a typical præcox and lacked so much common sense that psychoanalytic attempts elicited nothing more of value.

To my mind sex thoughts and reflection on sex matters did not cause the condition; rather are they to be considered as component parts of the complex symptomatology of the case. In this and similar cases the practical results obtained are negligible. We can manage to keep her out of the hospital but cannot influence her trends, for a restitution is not possible where the judgment and deeper personality are affected.

That without psychoanalysis it is possible to influence the trend and thought of a patient and achieve results is shown by the following case:

A girl of fourteen who graduated from public school, is bright and intelligent, became depressed, complained of constant headaches and insomnia. All that could be obtained from her sister by way of anamnesis is that last summer she went with a few other girls to Coney Island; they were in company of some fellows, had rides on the scenic railway; she was excited and later she saw a moving picture which scared her. The girl has been seen by a known neurologist, who prescribed bromides, but she did not show any change. As the family were poor she was brought to the mental clinic. The girl did not care to come, but after much urging, stepped into the examining room, sat down, morose. At first replied to a few questions, to others she refused to answer. Finally she exclaimed, "I don't care to go to doctors to be examined; it excites me." When I remarked that I did not mention to her any physical examination at all and explained to her the reason why she was brought to the clinic, she became mute. Finally she got up, began to take off her coat, saying, "I suppose I might just as well get through with it." There was evidently here a sexual conflict, no doubt a sex trauma preceded the condition. She unbuttoned and let me examine her chest. During the examination she kept her eyes covered with her hands. I began to chide her and lecture to her on the exaggerated modesty she exhibited and after a half hour she left for home. I told her that clinics are held twice a week and if she cared to call again in a week I would be glad to see her. To my surprise, she came in a few days, smiling, happy, and evidently greatly relieved. I made no attempt to obtain from her a statement as to the particular details of her upset and the actual mechanism involved. From a scientific standpoint much is left to be desired, but the practical purpose has been achieved.

Finally a word about the term Schizophrenia which Bleuler introduced and which means the splitting of the mind. Of course no such splitting as that observed in the double or multiple personalities in hysterical cases ever occurs. Only the unusual and rarely observed symptoms such as ambivalence can be said to approach this designation. Presumably when a patient gives both positive and negative answers to the same question, his psyche is split, one part is oblivious of the other's existence. I must confess that I have never been convinced of the truth of this assertion. This author maintains that every act or utterance of the præcox is motivated by complexes; the complexes form the nucleus of his disease, he is completely under their domination. If the analogy between dementia præcox and hysteria is so close, why is there such tremendous difference in their therapeutic possibilities? Bleuler was forced to assume an actual organic condition

underlying the psychosis, a toxemia presumably causing the loosening of associative connections. Of course, the whole thing is altogether speculative and is of interest only as such. Bleuler, among other things, mentions the blocking in dementia præcox and is of the opinion that these symptoms are due to complexes. No doubt that some idea precedes the blocking just as any activity or passivity can be said to have an adequate mental cause. But there the analogy between dementia præcox and hysteria ends. In the latter the cause operates systematically, continually, the result is constant; just as the winding up of the clock will result in a regular movement of the works. The cause is adequate and explains the symptoms; the symptoms explain the cause. There is no jolt, no startling factor, nothing that appears like a bolt out of a clear sky. The dementia præcox reactions, blocking included, cannot be predicted with certainty because they do not follow logical law, every bizarre, queer, startling reaction is possible. It is ingenious but useless to try to find some adequate explanation of the reaction of a præcox, only that can be explained which follows some definite law or rule. Where logical sequence is so disordered that prognostication is impossible, the reaction is incalculable, one can only speculate but not treat the subject with any degree of certainty. Bleuler likens the whole picture of dementia præcox to a dream; in a sense that is true, but the analogy does not go far since to the dream a definite meaning and interpretation has been given by Freud who demonstrated that the roots of the dream lie in the submerged life of the individual. The utterances of the præcox are fragmentary, disharmonious, have no relation to each other or to the totality of the ego. It is frequently extremely difficult to determine the conflicts and thoughts behind a dream. It is almost impossible to give a definite meaning to the jumble and jargon of a præcox.

I am reaching the end of my discussion this evening. I am conscious of the shortcomings. I have not offered anything positive, and the criticism I raised will be considered unnecessary and ill-founded. Perhaps so; in that case, if counter criticisms are made they will be welcome. Constructive thinking is difficult and requires more time than was at my disposal. What I have tried to bring out mainly is that current psychoanalytic thought is probably too bold in its assertions, a fact which is probably the result of its universal acclaim. I have brought no particular instances to support my assertion, having confined myself to generalities. At some future date I hope to return to the same subject again.

607 EASTERN PARKWAY.

GONORRHEA IN WOMEN.

BY ADOLPH JACOBY, M.D.

NEW YORK.

INSTRUCTOR IN GYNECOLOGY, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

OF all the venereal diseases gonorrhea is by far the most prevalent. It has been estimated that from 70 to 80 per cent. of the entire population has or at one time has had gonorrhea. This of course in-

cludes active and inactive cases. Women are affected in about the same proportion as men. Of the incidence of disease in women, gonorrhea takes a most prominent part, being responsible for more than 50 per cent. of all female pelvic inflammatory conditions.

There is some difference of opinion as to the site of the original infection in the female. When the infection results from an acute condition with plenty of gonococci in the discharge, the urethra and vulva being the first to come in contact with the infective material, would supposedly be involved first and most frequently. Infection as the result of transmission from a chronic case, with few or no gonococci in the discharge, would presumably involve the cervix most often. From a study of a series of cases among a group of women more or less exposed to infection,* it would appear that about 60 per cent. of infections are combined cervical and urethral; next in frequency are cervical alone, amounting to 30 per cent., and least often urethral infection, including only 10 per cent.

The symptomatology of gonorrhea in women is that of purulent inflammation anywhere, naturally modified by the location of the infection. In acute urethral infections there is usually a varying amount of burning and frequency of urination, and a certain amount of suprapubic discomfort or pain. In acute cervical infections the symptoms are not as a rule pronounced. There is usually a sense of fullness and discomfort in the pelvis, accompanied by a profuse discharge, which is responsible for an itching and burning sensation around the external genitals and in the vagina. There is in most instances, very slight constitutional reaction.

Objectively in urethral infections, there is more or less purulent discharge, which may be demonstrated by milking the canal from behind forward. In chronic infections this discharge may be limited to the glands which open into the urethra, especially Skene's glands situated close to the external meatus. The periurethral glands also frequently harbor infective material, when all active signs have disappeared from the urethra. It is therefore very important to strip the urethra forward to its very end, in order not to miss any discharge from these glands. The urethra is often thickened and hard as a result of periurethral inflammation, feeling like a pencil when rolled under the finger. Bartholin's glands are often involved, and it is usually possible to demonstrate small red areas around the mouths of their ducts; when the inflammation closes these ducts, abscess or cyst formation occurs. In the chronic cervical infections there are not many signs of disease present. There is invariably a mucopurulent discharge of greater or lesser quantity. Associated with this there may be erosion of the cervix, with inflammatory redness and hypertrophy and small cystic Nabothian follicles. As the inflammatory process extends, as it usually does through the lymphatics, it produces varying degrees of parametritis, as well as involvement of the tubes and ovaries.

In the report of smear examinations taken from the different sites of infection, many contradictory opinions are rendered. This I believe is due to the

*From examinations conducted at the Women's Court, New York City.

varying criteria demanded by different bacteriologist in making a diagnosis of gonorrhea from a smear stained by Gram's method; also to the number of examinations made, as well as to the time the smears are taken. In a series of examinations of 300 cases, only 8 had positive and 12 had doubtful reports, making together 20 cases, or 7 per cent. Of these same 300 cases, 100, or 33 per cent., were clinically diagnosed as gonorrhea. All of the positive and doubtful laboratory reports occurred among those so diagnosed. This gives a total of 8 per cent. if the positive laboratory findings alone are considered, and 20 per cent. if the doubtful cases are included, in the cases of clinical gonorrhea. When it is taken into consideration that practically all of these cases are of the prostitute class, it can readily be appreciated how very inefficient as a help in diagnosis is the usual smear examination. This is partly due to the fact that only one smear was examined. The proportion of positive smears is much greater when repeated smears are examined, or when taken just before or following the menstrual period, or even during menstruation, or when a Schultze tampon is left over night in close apposition to the cervix, and the collected discharge examined; or when the deep cervical glands are stimulated to pour forth their secretion by the application of negative galvanism for a few minutes. On reexamination of 50 of the cases of clinical gonorrhea which were placed under treatment, 47, or 94 per cent., showed positive smears, after an average of five smears had been examined in each case. This would make proportionately about 32 per cent. positives among the entire 300 cases examined. Even this is low. It at once becomes evident how utterly inadequate is a single smear report. Provocative stimulation by means of chemical irritation, although it increases the discharge, does not to any noticeable extent increase the number of positive reports. To isolate the gonococcus by culture is impractical. It grows very poorly on ordinary media, is readily overgrown by the other organisms usually present, and even when isolated, in the absence of pus cells, its identity is difficult without further subculture.

Further evidence of the unsatisfactory nature of the smear report is furnished by the transmission of infection from one individual to another. In the acute cases the contagiousness is high. In the subacute and chronic cases, although the contagiousness is less, the menace is greater, because less obvious. A chronic case with slight discharge, in which smear examinations are negative, during the engorgement at intercourse and the attendant outpouring of secretion from the depths of the glands, may readily transmit the infection to fresh soil. It should be remembered in this connection that in chronic cases the number of gonococci are few and that pus cells are usually numerous. It would be advisable then in any individual having a history of gonorrhea or in whom there is clinical evidence of a chronic gonorrhea, and in whom a smear examination shows the presence of numerous pus cells, without other organisms and without any gonococci, to consider the case one of gonorrhea and treat it as such.

The complications and end-results of gonorrheal infection contribute largely to the morbidity and

unhappiness of the female and often of the male. The extension of the inflammatory process to the bladder gives rise to cystitis. This is not very common because the urethra is practically a straight tube and the drainage is much better than in the male urethra, and also because it is not as often subjected to injections which tend to drive the infection further back, as is often the case in the male. The spread of the infection to the parametrial tissues, which occurs in nearly every cervical involvement, gives rise to a parametritis which may go on to the development of a pelvic abscess. Further extension through the lymphatics to the tubes and ovaries, gives rise to salpingitis and oophoritis often with abscess formation. The outer ends of the tubes are usually sealed by plastic inflammation resulting in sterility. In cases in which pregnancy does take place, ectopic gestation is very apt to occur. In the fulminating cases extension to the peritoneum gives rise to a general peritonitis, a rather rare and fatal condition.

In the treatment of the acute cases rest in bed for the first few days with general care of the bowels and diet, and with plenty of water to drink, is all that is necessary. Hyosciamus and sandalwood oil are very effective as sedatives to relieve the intense pain and burning on urination. Later, when the acute inflammation has subsided, an injection of 1 per cent. protargol or 20 per cent. argyrol into the urethra should be made every other day. In the chronic cases, the instillation of $\frac{1}{4}$ per cent. protargol or 1 to 10,000 silver nitrate into the bladder three times a week, in addition to the application of 5 per cent. silver nitrate to any ulcerated areas on the mucous membrane of the urethra through a Kelly speculum, is usually very effective in clearing up these inflammations. Special attention should be given to Skene's glands; direct application of 10 per cent. silver nitrate daily by means of a small hypodermic syringe, or, in obstinate cases, incision of the gland into the vagina or actual cautery of the gland is necessary. Of the more recent remedies, acriflavine in 1 per cent. solution as an injection into the urethra or instillation into the bladder, has given good results. Still more recently mercurochrome = 220, in the same strength and used in the same way as the acriflavine, is being extensively tried, and promises to be more effective than the older and better known antiseptics.

For the acute cervical infections, treatment similar to that in the urethral case is employed. The subacute or chronic cases are best treated by the application of 25 per cent. argyrol or 1 per cent. protargol to the cervix and cervical canal, not entering the uterine cavity, as well as to the vagina, followed by the introduction of glycerin and packing with gauze three times a week. The packing is removed at the end of 18 hours, and is followed by a hot douche. The douche is repeated two or three times a day depending on the amount of discharge present. For the douche a variety of drugs are used; permanganate of potash 1 to 5,000; tincture of iodine 1 to 500, acriflavine 1 to 5,000, and mercurochrome 1 to 5,000. Gonorrheal vaccine, 500-1,000,000 bacteria to the cubic centimeter, given 1 cc. hypodermically every five days, is a valuable aid in the chronic cases. In the treatment of complications extreme conservatism is advisable, operation

being resorted to only when absolutely unavoidable. It is seldom that a gonorrheal inflammation becomes sufficiently urgent to require immediate operation. As a rule, any operation fails to remove all infected tissue, thus necessitating long continued treatment after operation; this same treatment without operation is usually equally effective in its end results.

It has always been and probably always will be a very difficult problem to decide just when a case of gonorrhea can be considered as cured. It has been claimed that chronic gonorrhea in women is never cured. This contention, however, does not coincide with the usual experience. Treatment carried out faithfully along the lines suggested, and continued for a sufficiently long period, is generally effective in clearing up the majority of cases.

It has been deemed advisable that, before a case should be discharged from observation and treatment, at least the following conditions shall be carried out: It should be absolutely required (1) that all inflammatory discharge shall have ceased; (2) that at least six smear examinations shall be found negative, the smears having been taken from the cervix, the urethra, Skene's and Bartholin's glands; some of these smears should be taken just previous to, and some immediately following the menstrual period; (3) that smear examination made after provocative injection into the urethra shall be negative; (4) that a gonorrheal complement fixation test of the blood, although not of very great importance, shall be negative; (5) finally, that a reexamination, which shall include all of the above steps, after cessation of all treatment for a period of at least one month, shall again be found entirely negative. It is as much as can be hoped for in determining the absence of infection, if all of the above requirements are fulfilled. The future state of the individual physically and mentally, and in so far as she remains a possible source of infection, and thus a focus for the spread of the disease to the community, may depend largely upon the thoroughness with which the freedom from infection is determined.

HERNIA OF THE PLEURA COMPLICATING SPONTANEOUS PNEUMOTHORAX.

BY H. E. HALE, M.D.

NEW YORK.

IN my search of the literature, I have found no case even similar to the one I wish now to record. The nearest approach to it was reported by Maragliano,¹ in 1903 and again in 1904.

His patient had a left pleurisy with effusion. A thick-walled lump with sense of deep fluctuation developed close to the inferior angle of the left scapula. This gave a distinct impulse on coughing and could be reduced, with exception of the portion made up of the wall of the sac. With the removal of the reducing pressure, the sac immediately refilled, provided the patient was in such a position as to have the neck of the sac below the level of the fluid in the pleural cavity. Comparison of the fluids withdrawn from the pleural and hernial sacs completed the proof that they were communicating.

A very dissimilar, though equally interesting case is reported by G. R. Fowler,^{*} in 1889. His patient was a young child. The tumor presented in both sides of the front of the neck, most prominently, close under the left lower jaw.

Autopsy revealed a rupture of a primary bronchus in the right, upper lobe. The escaping air ascended, carrying the visceral and parietal layers of the pleura before it. It went high into the right side of the neck, then burrowed between the esophagus and the vertebral column, making its most conspicuous appearance, as before mentioned, high in the left side of the neck.

P. Fabre,[†] in 1886, reported a case of congenital "air diverticula in the front of the neck and at the superior middle portion of the thorax." In this case the defects were so gross as speedily to cause death.

Grateloup,[‡] in 1780, published an article entitled, "Observations on a Hernia of the Pleura." His patient was a woman of 24 years, who for ten years had experienced much abdominal pain, cramp-like in character. Later she developed a cough and pain in the region of the left sixth and seventh ribs. No mention is made of expectoration. In the course of a moderate time, an "oval swelling, 6.75 cm. by 2 cm., and of 2.5 cm. elevation, appeared in the sixth interspace. It came and went at will." It was soft and elastic and could be reduced by taxis. Operation was declined. Retention, with a pad and pressure, relieved the chest pain and cured the hernia, with improvement of her health.

V. A. Lebedeff,[§] reported a case of Hernia of the Pleura, in 1912. This patient had an empyema complicating pneumonia. Eight days after paracentesis, a fluctuating tumor, the size of a hen's egg, appeared at the site of puncture. This spontaneously disappeared the next day, but reappeared four days later still. It could then be felt immediately under the skin, to which it was not attached. It was movable, fluctuating, and gave impulse on coughing. One week after the second appearance, the swelling was incised. Only healthy tissue was encountered, and no pus and no cavity were found, as the swelling disappeared on incision. (I interpret this to mean the hernia, sac and contents were reduced en masse). Three days after this incision the swelling recurred, just below the cut. A needle, held parallel to the surface of the thorax, was introduced into the side of the mass and pus obtained. A second incision was then made with exactly the same result as the first, excepting that a few days after it pus began to escape through the wound. Autopsy revealed abscess of the right lower lobe of the lung, and an empyema.

My patient* was Dominick M——, a man thirty-six years of age. He had pulmonary tuberculosis with left, spontaneous pneumothorax. In the patient's back there was a semilunar tumor. It extended downward along the vertebral border of the left scapula, from a point about 8 cm. above the inferior angle, and upward and outward 9 cm. from the same angle. It was soft, compressible, though under some tension. To percussion it was

resonant. It could be almost entirely reduced, only to reform when pressure was removed. Coughing hastened the filling out and caused a perfectly plain impulse. This was evidently an air-filled, hernial sac of the pleura.

This patient did not feel very ill and after a few days in the ward, against urgent advice, left before a photograph was taken.

Medicolegal Notes.

Instructions as to Injured Spine Not Authorized by Evidence.—In an action for personal injuries an x-ray picture, introduced in evidence, was declared by a medical witness to describe a fracture of the fourth lumbar vertebra—in other words, a permanent injury to the spine. This x-ray picture was the subject of much controversy, and experts introduced on behalf of the defendant were in direct conflict with the plaintiff's expert on the matter of its interpretation. The plaintiff had refused to submit to a physical examination. No medical expert testified to injury to the spine, nor that the symptoms disclosed in the plaintiff's testimony could properly be assigned to spinal trouble. The plaintiff complained of pains in his back. This might be muscular as well as spinal; it might be rheumatism; it might be traumatic neuritis, secondary to an operation he had had for hernia; or it might proceed from any number of causes wholly unrelated to the spine. But the trial court in its charge invited the jury to determine "whether or not the accident caused an injury to the spine, and the extent of that injury even though the picture should not show it." This ushered the jury into the realm of speculation and permitted a finding based upon practically no evidence at all. Judgment for the plaintiff was therefore reversed by the Circuit Court of Appeals, Eighth Circuit.—Chicago, M. & St. P. Ry. Co. v. Holverson, 264 Fed. 597.

Finding of Accidental Injury by Contracting Anthrax at Factory.—In proceedings under the Illinois Workmen's Compensation Act for compensation for the death of an employee in a hide factory alleged to have resulted from anthrax contracted by accidentally coming in contact with the anthrax bacilli in the course of the employee's employment at the factory, there was no direct proof that there was, or ever had been, any hide in the factory infected with anthrax, but from the fact that the disease is primarily one which affects especially sheep and cattle; that its human victims are usually men engaged in handling wool, hides or animals; that the deceased was not at any place where he was likely to come in contact with anthrax except at the factory; that a pimple on his neck was scratched until it bled and the blood was wiped off with a towel; that he continued at work there and within the ordinary period of inoculation the neck began to swell and successive steps in the progress of the disease occurred, ending in death, it was held that an inference might justifiably be drawn that these results, thus following in regular succession, were a consequence of the only cause adequate to produce them which had been suggested, the existence of anthrax germs in the factory, showing that the deceased contracted the disease by an accident arising out of his employment.—Chicago Rawhide Mfg. Co. v. Industrial Commission, 291 Ill. 616, 126 N. E. 618.

New York, January 1, 1921.

THE GROWING ENSLAVEMENT OF THE PROFESSION OF MEDICINE.

Two correspondents in this issue of the *MEDICAL RECORD* call attention to two instances of governmental encroachment upon the freedom of medical practice. In the news column will be found a reference to other instances, especially to an attempt which will be made by the prohibitionists, emboldened by their assumed success in cutting off the use of alcoholic beverages, to forbid the use of alcohol not only in patent medicines but also in legitimate tinctures and elixirs. Under the present interpretation of the Eighteenth Amendment a physician can prescribe only one pint of whiskey or brandy every ten days for each patient. If a patient with septic fever needs any alcohol at all, he needs more than six drachms a day, but that is all the lay regulators of medical practice will permit him to have. If a man in the country is seized with renal colic twenty miles from a drug store and his companion happens to be a physician, the latter cannot telephone to that drug store for morphine, but must write a prescription on the official blanks, which he probably has not with him, and then must go himself to the drug store and prove his identity before he can get the drug, his friend with renal colic meanwhile having a good time by himself, twenty miles away.

Whether the compulsory reporting of venereal disease is for the good of the community is a question as to which there are still two sides. Whether a physician who is uncertain regarding some provision of the wretchedly drawn Harrison law shall put off prescribing for his patient until he can have the point decided by the courts, or shall prescribe as common sense and his conscience dictate, is a point for him to settle at his own risk. Every year an attempt is made in the New York Legislature to pass a bill compelling licensed physicians to register themselves each year and pay a tax under penalty of losing their right to continue the practice of their profession. The antivivisectionists and the antivaccinationists we have always with us. Nearly every year some new group of "healers," with little education or no education, are recognized by some State Legislature and are made by law the equals of medical practitioners who have given years of study to qualify themselves to treat the sick.

Who is to blame for this ever-increasing interference with the liberty of medical practitioners? If the medical societies of the land—county, State, and national—were conducted as they should be and exercised the influence that they readily could if their officers were in general more alive to their responsibilities, possibly a halt might be called to this meddling by politicians and cranks with the practice of medicine.

THE CHILD HEALTH CENTER AND THE MUNICIPAL NURSE.

THERE can be no doubt, in the most skeptical mind, of the success of municipal child health centers, or, as they are sometimes called, baby welfare stations. Beginning as they do, and as they certainly should, with prenatal care, these clinics present to the young mothers of the poorer classes the opportunity to give their infants and children the benefit of modern medical supervision. In cities where they have been established in sufficient numbers, they have the decided advantage of availability. To be successful, a place for keeping well babies well must not be too far from home. Many mothers will travel considerable distances to some large clinic or hospital in order to "get the best for the baby" when he is sick. Very few would take that trouble to have a well baby weighed, or to put an early stop to "a little running of the bowels."

Prophylaxis makes the least appeal of any of the medical sciences. Hence the antivaccinationists. But anyone who sees even a few infants will realize the importance of checking "a slight diarrhea" at the earliest possible moment, of discouraging that deep-rooted love of giving the baby anything from a can with directions on the outside, and of explaining to the mothers the proper methods of feeding and care. Protection against preventable illness would seem to be the birthright of every baby. It is for this that the baby welfare stations stand—whether the disease be diarrhea or diphtheria. The large clinics and hospitals should be the places where sick babies are treated. It should be the function and aim of the baby welfare stations to deprive them of material. This, any close observer of their work will agree, is exactly what they are doing.

The greatest obstacle to the success of baby welfare work is, strangely enough, very often the mother of the baby. Like the rest of the world, she has a lazy aversion to the prevention of calamity, whether it be war or disease. No matter how near the clinic, no matter how "good" the doctor, she simply does not care to bring the baby in for observation. Far better take the advice of grandma, or of the neighbors, or of labels on cans! Only a sick baby needs a doctor.

For protection against this maternal apathy, the baby must rely upon that indispensable medium between doctor and patient—the nurse. Competent visiting nurses, to urge attendance at the clinics, to see that the doctor's orders are carried out, are essential to the success of the welfare stations. It is very clear that where infant welfare work has

met with signal success, a well organized and efficient corps of municipal nurses is sure to be found.

Many mothers, of course, do not require constant urging to do the right thing for their babies. These regard the clinics as a present help, and are glad of observation and advice. Obviously it is the irresponsible, rather than the responsible mothers, who must be nagged and lectured and watched by nurse and doctor. It is still all too plain which class of mothers is in the majority.

PROGRESSIVE SPINAL MUSCULAR ATROPHIES OF SYPHILITIC ORIGIN.

PROGRESSIVE muscular atrophy of the Aran-Duchenne type, classically described as chronic anterior poliomyelitis, has syphilis as an extremely frequent causal factor. The great majority of cases of so-called chronic anterior poliomyelitis are, in reality, amyotrophic syphilitic myelitides. Clinically, syphilitic amyotrophy assumes the ordinary characters of amyotrophy, namely, a progressive evolution, an almost constant localization in the upper limbs; the existence of fibrillary contractions and the reaction of degeneration; usually with absence of disturbances of the sensibility and sphincteric functions. It also manifests itself by the frequent occurrence of pain more or less directly related to syphilitic meningitis, and especially by signs of spasmodicity, such as exaggeration of the reflexes, epileptoid trepidation, with or without extension of the toes, indicating a diffusion of the syphilitic process in the lateral columns of the cord. The clinical picture frequently becomes complicated by the association of medullary or encephalic syndromes of syphilitic origin, such as tabes or general paralysis of the insane. Finally, in the majority of cases the presence of signs or stigmata of syphilis are generally noted, such as specific cicatrices, the Argye-Robertson sign, unequal pupils, iridochoroiditis, aortic insufficiency, etc., which, combined with the lymphocytic count and Wassermann reaction, render the diagnosis of syphilitic amyotrophy an easy matter.

Pathologically, the process is not an anterior poliomyelitis, but is a diffuse vascular meningomyelitis. Atrophy of the interior horns is purely secondary and is constantly associated with more or less marked lesions of the white matter, vessels and meninges. At the onset the lesions consist of a lymphocytic infiltration generalized to all the parts composing the cord and its envelopes; the vessels are encased in a cuff of lymphocytes. Later on, the infiltration often disappears, leaving in its stead more or less pronounced lesions of sclerosis; fibrous thickening of the pia and connective tissue partitions, proliferation of the neuroglia, endoperiarteritis without any specific character, and sclerosis of the white columns. The latter lesion is particularly frequent and may be seated either in the anterolateral columns or in the crossed pyramidal fasciculi.

The favorable results so frequently obtained by resort to modern specific treatment should make it

incumbent on every physician to resort to it in each case of progressive amyotrophy. This treatment will often arrest the progress of the lesions and in still more fortunate cases it is susceptible of producing a more or less considerable retrogression of the atrophy, and occasionally a total and permanent cure may even be brought about.

ENTERO-ANTIGENS IN PRACTICE.

SEVERAL years ago Danysz of the Pasteur Institute of Paris introduced into the treatment of anaphylactic affections the use of cultures prepared from the intestinal contents of the patient. He calls this and analogous plans of treatment "curative antianaphylaxis." Under the conditions amenable to this kind of treatment he places psoriasis, asthma, and enteritis. His antigens for psoriasis are obtained from a number of patients and herein his method differs from that originally described which was purely a matter of autovaccination. The cultures from the intestines of 25 psoriatics were composed of a special strain of colibacillus, streptococci, staphylococci, enterococci, sarcinae, and one anaerobic organism with spores, and were used for psoriasis only, but in the preparation of a general polyvalent vaccine he got the best results from a mixture of two kinds of coli bacillus, one each of staphylococcus, streptococcus, and enterococcus, and the *B. proteus*. All of the strains are not only non-pathogenic but are sterilized by heat or ether or some other method. Danysz does not claim any advantage in theory for these preparations over simple peptones, milk, or various sera, but he does insist that the fact of obtaining cultures of microorganisms gives a better product for the practitioner. The only contraindication to this form of medication is fever, though this is not really a contraindication in the ordinary sense but the remedies are not indicated in chronic affections with fever. The dose of the hypodermic may be as small as a thousandth of a milligram, and a tenth of a milligram produces a disagreeable reaction on buccal ingestion. The fact that such small doses of culture are efficacious when given by the mouth suggests specific activities, although these are not claimed.

THE WASSERMANN REACTION IN THE TRANSUDATES OF SYPHILITICS.

RISER has studied this subject in the internist clinic at Toulouse, his results appearing in the *Annales de dermatologie et de syphiligraphie* for October, 1920, i, 10, this volume being the first of the sixth series. In 1910 Roger and Sabareanu investigated blister serum extensively for the Wassermann and apparently made a study of spontaneous exudates. In 1912 several studies were made of the transudate in syphilitic hydarthrosis. No details are given concerning the finds of Roger in exudates, but the author evidently built on their foundation and his first cases were in cardiorenal syphilitics with pleural and ascitic accumulations. In the first subject tested there were no organic lesions of syphilis. The blood serum, edema punctate, and hydrothorax punctate all gave a positive reaction. However, a second test made some time afterward gave weakly positive or negative results. In the second patient

of the same type, the results were the same for the first puncture. As the exudates were absorbed rapidly under digitalis and theobromine there was no opportunity for a second test. The third syphilitic died of pleurisy and no evidences of syphilis were found at autopsy. The pleurisy was of the ordinary type. The serum and pleurisy punctates had both been positive. In all 6 patients of this type were studied and in all the blood Wassermann was positive. The first five cases narrated also showed positive punctate reactions. The sixth patient with the same clinical finds had negative punctates. In five other patients with chronic nephritis only, various punctates were positive. It is evident that the reacting substance does not remain permanently in the transudate, which may explain negative results.

PSYCHOGENIC TETANUS.

TETANUS has at times been simulated, but documents to this effect are very rare. Chavigny of Strasbourg, however, has seen no less than 3 cases of this type (*Progrès Médical*, Sept. 18, 1920, xlviii, 38). The first was in a soldier hit by an infantry bullet who did not develop symptoms of tetanus for 6 months. He received intensive serum treatment, but apparently the condition persisted without any tendency to a serious termination. It was found that he had lived in constant fear of the disease and that the symptoms did not supervene until he had witnessed the death of a tetanus victim. Moreover the victim was a comrade who had been wounded in the same affray as himself. The tetanus contractions subsided after the man had been reasoned out of his delusion. The prolonged incubation or latency, the superposition of the symptoms at a psychological moment, and the absence of any malignant disposition on the part of the disease, together with the psychical cure readily distinguished the condition from true tetanus. In the second case there was a history of a supposed authentic tetanus at the age of 17, treated at the Pasteur Institute. Just one year later the disease reappeared, forming an example of so-called "anniversary tetanus." There was no history of a wound. Doubt was then thrown on the authenticity of the first attack, although there was no way of proving or disproving it. In the third case a man wounded in the face developed trismus, which persisted indefinitely without aggravation or generalization. It was recognized as hysterical. The subject was anesthetized, the jaws separated and a cork interposed between them. On waking the patient was cured.

News of the Week.

Drastic Rulings on Prescriptions for Narcotic Drugs.—Walter R. Herrick, State Narcotic Drug Control Commissioner, has announced two new rulings designed to further limit the illicit use of narcotic drugs. One ruling eliminates the use by doctors of the unofficial prescription blanks for administering any narcotic drugs. No such drugs can be prescribed by a doctor, whether for drug addiction or otherwise, except on official blanks issued by the department. This ruling was made because the bulk of the abuses in the dispensing of

drugs has been through the use of unofficial blanks. The second new regulation compels doctors administering to an addict to ascertain who was the last doctor who treated him. This gives the department a complete history of an addict and makes easy his arrest and conviction in case of false representation which is a misdemeanor.

No More Tinctures.—The prohibition lobby in Washington is reported to be laying its plans to have Congress pass a law forbidding the use of alcohol in the preparation of medicines. The object is publicly stated to be the suppression of the host of "bitters" and other patent medicines which are largely used for beverages in place of the liquor which can be had only at considerably greater cost. Privately it is suggested that many of the preparations of the U. S. Pharmacopœia and the National Formulary will also be wiped out if the lobby attains its end.

Harrison Law Conviction Affirmed.—The United States Circuit Court of Appeals handed down a decision, on November 16, 1920, affirming the conviction of Dr. Solomon Rothman, a physician, and Louis and William Cohen, druggists, for violation of the Harrison Law. The defendants were sentenced to two years in the Atlanta Penitentiary, but have been out on bail pending their appeal. The Government's position, on all the legal points raised, was sustained by the opinion of the court, which was unanimous. The most important point decided was that a United States Treasury regulation, construing the law, has no bearing on the case, if it is contrary to a subsequent court decision.

Smoking in Public Assailed.—Dr. Royal S. Copeland, Health Commissioner of New York City, has issued a statement declaring that there should be an organized movement against smoking in public restaurants at normal eating time, in offices where non-smokers are employed, and in every public place where smokers and non-smokers are found. Dr. Copeland calls attention to the dangers of nicotine applied to the human system, and the deadly influence of the half-consumed cigar butt. He scores as "contemptibly" selfish the smoker who contaminates the atmosphere of eating places frequented by non-smoking persons.

Smallpox on Incoming Vessels.—Two cases of smallpox have recently been discovered on incoming vessels. One of these was among the 1,357 steerage passengers of the *Duca d'Aosta* and the other was among the 1,400 steerage passengers of the *Duca d'Abuzzi* of the Italian Royal Mail Line arriving on December 23. Plans to have these immigrants passed at Philadelphia because of the congestion at Ellis Island were changed and these passengers held at Quarantine.

Hospital for Seoul.—Influential Koreans have filed a petition with the authorities of Seoul for permission to establish a modern isolation hospital in that city. Funds totalling \$100,000 for the erection of the hospital will be raised by public subscription.

Brooklyn Hospital Sells Property.—The Brooklyn Eye and Ear Hospital has sold its property to the Polytechnic Institute for \$150,000, of which \$20,000 is to be in cash. The hospital directors are negotiating for the purchase of a site for a new hospital on Greene Avenue between Carlton Avenue and Cumberland Street, Brooklyn.

Dr. Charles A. Powers of Denver has received by direction of King Albert of Belgium, the Decoration of Officer of the Order of Leopold, awarded for conspicuous service in the World War.

Paris Academy of Medicine Celebrates Centenary.—The Paris Academy of Medicine celebrated its one-hundredth anniversary on December 20. President Millerand presided and representatives of nearly all the countries of the world, including the United States, Great Britain, Italy and Spain, were present.

Paris in Need of Radium.—The French Parliament has been asked to authorize the purchase of two grams of radium at a cost of 2,000,000 francs. One gram is available in Madame Curie's laboratory and the other will have to be purchased either in London or New York.

Appeal for Louvain Library.—Dr. Nicholas Murray Butler, who is head of the executive committee for the reconstruction of the Louvain Library, is making an appeal for funds for this purpose. A site for a new library has been chosen and the architect selected, but in the months during which a campaign for funds has been under way only about \$150,000 has been raised. The authorities at Louvain are inquiring whether substantial aid may be expected from America.

A Plea for Blinded British Soldiers.—Dr. Arthur Pearson, Chairman of the Blinded Soldiers' and Sailors' Care Committee, is soliciting funds for the support of the work for blind soldiers and sailors being carried on at St. Dunstan's, England. Here 2,000 blind men are cared for and taught occupations that enable them to reconstruct their lives. Besides those actually blinded on the battlefields, 23,000 men were discharged from the army with seriously damaged sight, and many of these have found it necessary to come to St. Dunstan's. Dr. Pearson states that their plans for helping the blinded soldiers back to a normal life have worked out better than any one dreamed would have been possible. He feels that recalling to the public what this work means to the blind cannot fail to bring the funds necessary to the proper maintenance of the activities of this institution.

Rockefeller Foundation Aids Czecho-Slovakia in Public Health Program.—The International Health Board of the Rockefeller Foundation announces a cooperative program in public health, agreed upon with the Government of Czecho-Slovakia. This program provides: (1) Lending to the Czecho-Slovak Government the services of an American competent in Public Health Administration. (2) Fellowships for training a select group of young Czechs for service in the field of public health. (3) Cooperation in the development of a national public health laboratory service. (4) Expense of a Czech Commission to study public health administration in the United States. Fellowships have been provided to enable nine medical representatives from Czecho-Slovakia to pursue courses in public health, hygiene and preventive medicine in the United States for 1920-1921. Those accepting the preferred courses agree to serve the Ministry for from three to five years after their return from America. Five members of the commission from the Ministry of Hygiene of Czecho-Slovakia have recently arrived in America as guests of the Foundation. They will make a tour of the country,

which will include visits to Baltimore and Washington, scenes of rural health work in North Carolina, and Boston, Albany, Saranac, Toronto, New York, Chicago, and Columbus, Ohio.

Doctors and Nurses Give Play.—The medical, surgical and nursing staffs of the Post-Graduate Hospital gave a play, followed by a dinner and dance, at Delmonico's, on the evening of December 23, in aid of the endowment fund of the hospital. The play, entitled "There's a Reason, and Effervescence in Three Syphons," was written by Dr. Marvin Jones.

Scientific Feeding Experiments on School Children.—To determine why thousands of Detroit school children are undernourished and how undernourishment in school children can be overcome, city officials, assisted by charitable organizations, will begin in January a three months scientific feeding experiment on two groups of fifty pupils each. The group of fifty undernourished children will be served the regular hot noon luncheon which is sold at some of the schools. The homes of these children will be visited to determine whether the malnutrition is the result of physical defects, inability or neglect of parents to supply proper food, improper food selection, lack of home discipline, or dislike of the children for proper food. As a check, fifty undernourished children in another school will be selected for a similar experiment except that they will not get the hot luncheon. In this way it is hoped to arrive at the relative value of two kinds of luncheons served the children.

The Burden of the Alien Mental Defective.—In an address before the forum of the Church of the Ascension, on December 19, Dr. Pearce Bailey, Chairman of the Committee on Mental Defectives in New York City, urged the need for more educational and institutional facilities for the care of the 40,000 mentally deficient in New York State. It has been found that 31 per cent. of the persons in New York State with subnormal brain capacity are foreign born. In view of this fact, Dr. Bailey believes it is imperative to find some means of keeping out mentally defective aliens.

Abandon Plans for Police Hospital.—It has been announced by Coleman du Pont, chairman of the police hospital fund, that opposition to the proposed hospital had led to the abandonment of the project, and that the money raised will be turned over to the police relief fund.

Surgery by Radio.—According to a recent account in the *New York Herald* the correspondence school has been outdone. This report tells how the Belgian steamship *Menapier*, battered by a hurricane, sent out an S. O. S. message requesting medical aid. The *Winifredian*, several days out en route from Liverpool to New Boston, picked up the message, but as the sea was too rough to permit the launching of a boat to send medical aid, Dr. Patrick S. Burns of Providence, surgeon of the *Winifredian*, received by wireless details of the men's injuries, and dictated the treatment for broken arms, legs, and other injuries. For three days the two vessels lay within hailing distance while the surgeon's instructions were obeyed. On the fourth day the *Menapier's* captain sent word that all instructions had been carried out and the injured men were resting comfortably and apparently out of danger.

Gift for Blind Soldiers.—William Nelson Cromwell, President of the Blind Relief War Fund, has made a Christmas gift of \$5,000 to this organization.

Far East Medical Congress.—A meeting of the Far Eastern Medical Association is to be held in Batavia, Java, in August, 1921, according to an announcement made by Alejandro Albert, secretary of the Department of Public Instruction of the Philippine Islands.

Boston Meeting of the American Medical Association.—The local Committee on Arrangements for the annual meeting of the American Medical Association, to be held in Boston, June 6-10, 1921, has been organized as follows: *Chairman*, Dr. F. B. Lund; *Secretary*, Dr. Richard H. Miller. *Subcommittee on Finance*: *Chairman*, Dr. Hugh Williams; *Secretary*, Dr. Channing Frothingham; *Treasurer*, Dr. A. William Reggio. *Subcommittee on Sections*: *Chairman*, Dr. William H. Robey, Jr.; *Secretary*, Dr. H. Archibald Nissen. *Subcommittee on Exhibits and Printing*: *Chairman*, Dr. D. F. Jones; *Secretary*, Dr. George Gilbert Smith. *Subcommittee on Hotels*: *Chairman*, Dr. John T. Bottomley; *Secretary*, Dr. Stephen Rushmore. *Subcommittee on Entertainments*: *Chairman*, Dr. C. A. Porter; *Secretary*, Dr. A. W. Allen. *Subcommittee on Registration*: *Chairman*, Dr. A. S. Begg; *Secretary*, Dr. Samuel R. Meaker. *Subcommittee on Clinics*: *Chairman*, Dr. J. C. Hubbard; *Secretary*, Dr. R. S. Eustis.

Nurses Need Housing Accommodations.—Some time ago the Central Club for Nurses was organized and with the help of the Y. W. C. A. a club building costing about half a million dollars was erected at 61 Lexington Avenue, New York. This building is no longer adequate to the demands made upon it. In view of the fact that many unattached and inactive nurses availed themselves of this opportunity to obtain a home the accommodations for younger and active nurses have been greatly curtailed. To meet the situation thus created a ruling has been made whereby each and every nurse who has occupied rooms for a certain period must vacate. In view of the inconvenience which this arrangement causes the nurses are making a plea for another club. They point out that the Central Club has been a money-making proposition from the start, and are initiating a campaign for a membership of two or three hundred and a fund of \$15,000 to \$20,000 with which to extend the activities of the Club.

Visiting Nurse Service Appeals for Funds.—The Henry Street Settlement has appealed for funds to enable it to keep its nurses in the field. The nursing force is at present totally inadequate to handle the flood of calls for help which are pouring in, and it is anticipated that when unemployment has made conditions more acute far greater demands will be made upon the Visiting Nurse Service.

Dr. Haven Emerson, formerly Commissioner of Health of New York City, has been appointed to the position of Medical Advisor and Assistant Director of the Bureau of War Risk Insurance.

Obituary Notes.—Dr. JAMES THOMASSON MOREHOUSE of West Orange, N. J., died in the New York Hospital from the result of x-ray burns received fifteen years ago, on December 20, at the age of sixty-three years. Dr. Morehouse was graduated

from the New York College of Pharmacy, in 1879, and from the Medical Department of New York University, in 1893. He has been interested in x-ray work since 1895.

Dr. WORTHINGTON W. MINER of Ware, Mass., died on December 19 of pernicious anemia. He was born in Ware, November 5, 1847, of a medical family, his father and his uncle both being surgeons. After obtaining his degree from the University of Buffalo in 1871, he practised for eight years as assistant to his uncle in Buffalo, being also attending surgeon to the Sisters of Charity Hospital and associate editor of the *Buffalo Medical Journal*. In 1880 he removed to Ware and there practised his profession up to within six months of his death. He was surgeon to the Boston and Maine Railroad and was a member of the New York and New England Association of Railway Surgeons, the Hampshire District Medical Society, of which he was president in 1908-9, the American Medical Association, and the Massachusetts Medicolegal Society.

Dr. NATHAN SMITH DAVIS of Chicago, son and namesake of the founder of the American Medical Association, died on December 21 of lymphosarcoma at the age of 62 years. He was a graduate of the Chicago Medical College in 1883. For a number of years he was dean and professor of the principles and practice of medicine and clinical medicine in the Northwestern University Medical School, and was attending physician to the Mercy, St. Luke's, and Wesley Hospitals. He was a member of the Cook County Medical Society, the Illinois State Medical Society, the American Medical Association, the Chicago Pathological Society, the Chicago Neurological Society, and the Chicago Institute of Medicine.

Dr. JOHN W. HANNA of Winfield, Iowa, died December 2 from cerebral apoplexy, at the age of 73 years. He was a graduate of the Iowa State University Medical School in 1873.

Dr. SYLVESTER D. WILLARD died in London, England, on November 28, at the age of fifty-six years. Dr. Willard was born in Albany, N. Y., educated in London, and took his medical degree at St. Bartholomew's Hospital.

Dr. HERMAN HELLENSTEIN of New York, died at Mount Sinai Hospital, on December 20, at the age of fifty-seven years. He was graduated from the University of Buffalo, in 1890, and was Coroner of Manhattan from 1909 until that office was abolished in 1917.

Dr. WILLIAM J. SWIFT of New York City, a graduate of the College of Physicians and Surgeons, in 1878, died suddenly, on December 20, at the age of fifty-eight years.

Dr. ALFRED EUGENE SPALDING, a graduate of the University of Pennsylvania, in 1874, died of pneumonia at his home at Luverne, Minn., on December 4, at the age of sixty-nine years. He has for many years been a member of the Council of the Minnesota State Medical Association.

Dr. WILLIAM F. M. SOWERS of Washington, D. C., died at his home on December 19 at the age of forty-six years. He was graduated from Johns Hopkins University, 1907, was a Fellow of the American College of Surgeons, and a member of the American Medical Association. He was a member of the surgical staff of the George Washington, Providence, and Foundling Hospitals.

Correspondence.

METEORIC CONDITIONS IN RELATION TO CORYZA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In an article published December 6, 1919, Dr. C. M. Richter designates the following among his conclusions concerning the spread of coryza:

2. It (coryza) develops therefore principally during the cyclonic weather condition called low, especially when a period of very dry weather has preceded a low and when, in consequence, the change from previous dry air to the incoming very moist air is most rapid.

It may be added that the "period of very dry weather" is a period during which the dustiness of air, for want of a better name, the "blue haze" is most apparent. The haze is not always apparent, but usually is discoverable within a very few days after the midday humidity runs below normal. The haze increases from day to day until the horizon is greatly discolored—frequently a leaden color.

The color of haze particles depends very largely on their size; in general, the finer the particles, the more distinctly blue the haze becomes. Particles of the blue dust haze are finer than the smoke from the burning end of a cigar—very much finer than the exhaled smoke. The highest power of the microscope does not discover them. They belong to the floating dust of the air; if they are brought to the ground it is by means other than their own gravity. If they fall, it is because they become nuclei of condensation. The fact that the blue haze is apparent at times immediately after a rain is evidence that some of the particles, at least, are not brought to the ground, and also that they are not "favorable" nuclei.

The constitution of the particles is not known. Probably they consist of any sort of matter that gets into the air and is reduced to the fineness of haze matter.

Here is the interesting point: Slides exposed to air free from wind-blown dust, if placed in clean, moist air, develop colonies of microorganisms even under standard conditions of isolation. It is not unreasonable to infer that they develop from floating spores that do not come from ordinary wind-blown dust. There is but little doubt that a period of several days of wind-blown city dust is followed by onsets of pulmonary disorders; my own experience, which is that of a layman, is that a few days of haze weather will account for the prevalence of colds that usually follow.

J. W. REDWAY.

METEOROLOGICAL LABORATORY,
MOUNT VERNON, N. Y.

SOME THOUGHTS SUGGESTED BY THE CAMPAIGN AGAINST VENEREAL DISEASES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I am in receipt of the following letter, which is the occasion of this communication. "Dear Doctor: On looking over the list of physicians who have reported their venereal diseases regularly, I fail to find your name among them. We feel sure that this oversight on your part is not deliberate,

but rather, in the rush and turmoil of a busy practice you have simply overlooked this important duty. Paragraphs 1 and 2 of the venereal disease regulations of the State Board of Health especially set forth that venereal diseases are communicable and dangerous to the public health and shall be reported by serial number only to the local health officer. There is not a case on record where any individual, who has complied with the law has been molested or any publicity given him by having his cases reported by other than serial number, etc." Signed by the "Director, Bureau of Control of Venereal Diseases, U. S. Public Health Service."

Our Arizona law provides that the patient shall first be reported by serial number; that he shall continue under treatment, until repeated Wassermann reactions, in the case of syphilis, and microscopic examinations, in the case of gonorrhea, show that he is free from disease. During such time he shall be considered to be in "quarantine." In case he fails to comply, literally, with these provisions of the law, he is to be reported by his physician, by "name, address and serial number," to the State Board of Health and "becomes liable to the penalties provided for, etc." So much for the patient. Now for the physician. "Any physician, health officer or other person, violating the provisions of these regulations or refusing to obey the instructions herein contained shall be guilty of a misdemeanor and subject to the penalties of the Public Health Act."

Thus the physician is held responsible for the individual acts of his patient and for the complete treatment of these diseases, extending over months or even years and, until laboratory tests show that he is entirely well. If the patient, for any reason, carelessness, ignorance or lack of funds, does not follow up the treatment, his physician, whom he consulted, in confidence and as his friend in need, is supposed to become a police officer, a spy on his movements, a traitor to his confidence and report him to the health authorities by "name and address," subjecting him to all kinds of injury, economical, moral, and social. No conscientious physician wishes to be placed in the position of threatening to report his patient if he fails to continue his treatment, thus forcing him to an expense that he, the patient, may think unnecessary and will, almost certainly in some cases, consider a species of blackmail. The physician is thus placed in the dilemma of either working for nothing or violating his professional relations to his patient, and, I think it safe to say, that most physicians will do neither. I am sure I can speak for the older generations, who, upon graduation, took the "Hippocratic Oath."

This class of physicians will quit the treatment of venereal diseases or even the practice of medicine, before they will thus violate their most sacred obligations. It is no answer to say "There is not a case on record where any individual, who has complied with the law, has been molested or any publicity given him, by having his case reported by other than serial number."

The proposition that the physician has to face is not the failure of the health authorities to fully enforce the law; but that he is asked to violate the most solemn of professional prerogatives, "professional secrecy." Is it possible that all patients have obeyed the law, the doctors too, and that no one

has been reported by "name and address" to the Board? There may be, possibly, no objection to the report by serial number, alone, if wanted for statistical purposes; but I confess that I would dislike to die suddenly and leave in my desk a private record with "serial number, name and address" of Mr. A., B., or C., perhaps one of the most prominent members of the community, including, possibly his wife, with a diagnosis of syphilis or gonorrhea. The whole thing is wrong ethically and constitutionally.

So much in the way of adverse criticism: now as to constructive suggestions. It is to the profession and the profession alone, that we must look for the successful working out of this question, and this cooperation must be obtained, with the voluntary consent of the profession and without drastic laws that interfere with the physician's or patient's personal liberty of action. With patients of intelligence and those who have the means to follow out the necessary treatment, the friendly admonition of the physician will accomplish all that is possible. The trouble is with the other and larger class, the ignorant and indigent or semi-indigent, who fear that they cannot afford the expense or are unable to appreciate the physician's forecast of the disastrous results of neglect of treatment. For these last the State might, upon the simple statement by the physician of the circumstances, furnish the necessary medicines, and I am glad to say, this is already being done.

Now, for a few remarks along broader lines. I am not an alarmist on the subject of syphilis, to the extent that many are, though free to confess that it is bad enough. It will never destroy the human race. Humanity, at large, at the present time, is pretty efficient, I should judge, as the result of the experiences of the last few years on the battlefields and in other directions, and certainly syphilis has had plenty of time to demonstrate its general average effect on the race. The ever-increasing importance attached to it by the profession will continue to act as a factor in its further control, even along the lines of a slow social evolution. Whatever is done to support the profession in its efforts must be done along these natural evolutionary lines and not by drastic, sumptuary laws that infringe on personal liberties. I trust that no one will misjudge the spirit or intent of what I have written. It is, in no sense a protest against the campaign for the eradication of venereal disease. It is a protest against some of its methods of procedure and especially against the insidious conceptions, German in origin and Bolshevik by extension, that the individual has no rights that the State is bound to respect. I am willing to be convinced, if anybody can show me that the argument is not sound from any standpoint, either professional, ethical, or constitutional.

F. CAUTHORN, M. D.

SUPERIOR, ARIZ.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Following its established policy of giving in *extenso* decisions of the courts relating to the conviction of physicians for alleged violations of the Narcotic Laws, the Weekly Bulletin of the Department of Health, New York City, prints the following article in its issue of Dec. 11, 1920:

The United States Circuit Court of Appeals handed

down a decision, on November 16, 1920, affirming the conviction of Dr. Solomon Rothman, a physician, and Louis and William Cohen, druggists, for violation of the Harrison Law. The trial took place before Judges Rufus and Foster, and the defendants were sentenced to two years in the Atlanta Penitentiary, but have been out on bail pending their appeal. This decision of the Circuit Court of Appeals is the first to be rendered in the cases of physicians (four), convicted of similar offenses in 1919 and 1920, and all of whom appealed. The government's position, on all the legal points raised, was sustained by the opinion of the court, which was unanimous. The most important point decided was that a U. S. Treasury regulation, construing the law, had no bearing on the case, if it was contrary to a subsequent court decision.

In a similar article, "Physicians and the Harrison Narcotic Law," contributed to the *Journal of the American Medical Association*, Arthur D. Greenfield, Attorney and Counsellor at Law of this City, elaborates this decision in the following words:

Several points of more or less technical legal interest were decided, but the feature of the decision which is of particular importance to physicians and druggists relates to the power given by the Harrison law to the Commissioner of Internal Revenue, with the approval of the Secretary of the Treasury, to make rules and regulations. The court held that this gives no authority to make rulings interpreting the law; that a physician relying on any interpretation of the law made in a departmental ruling does so at his peril, and cannot plead that he was misled by it if the courts should subsequently decide that the ruling was wrong. . . . I am told that after the Supreme Court decisions on the Harrison law were rendered, in March, 1919, the officials of the Internal Revenue Bureau were subjected to great pressure from physicians and others desiring interpretations of the law, and were not only urged to issue general rulings but received innumerable requests from individuals for advice on their particular problems. This decision may help to impress on physicians that if the text of the law in any particular is not sufficiently clear to enable them to decide safely what their rights and duties are, they should either have the question tested in the courts or else try to have the law amended so as to make it clear. Appealing to administrative officials for an interpretation is of no benefit, and reliance on such interpretations may prove dangerous.

One of the paragraphs from the Court's charge as given to the jury is as follows:

Assuming that these Treasury Decisions conflicted and that Decision No. 2200 was wrong and Decision No. 2879 was right and in accordance with the decision of the Supreme Court in *Webb and Goldbaum v. United States*, 249 U. S. 96, the trial judge was bound to disregard No. 2200; the meaning of the act is authoritatively determined by the court and not by the Treasury Department. Ignorance of the law excuses no one. It could be no excuse that the defendants relied on a Treasury Decision which was wrong. In the *Webb* case it was authoritatively settled that if a practising and registered physician issues an order for morphine to an habitual user thereof, the order not being issued by him in the course of professional treatment in the attempted cure of the habit, but for the purpose of providing the user with morphine sufficient to keep him comfortable by maintaining his customary use, such order is not a physician's prescription under exception (b) of Section 2 of that act. The instruction given by the court conformed to the ruling of the Supreme Court and there was no error in refusing the instruction requested.

Summed up, the situation as it now stands practically amounts to this: Under a Revenue measure the Government taxes the hundred and fifty thousand physicians of the United States three dollars a year each for the privilege of prescribing narcotic drugs. It entrusts the administration of this law

to Treasury and Internal Revenue officials. These officials as agents of the Government make rulings interpreting these laws and setting forth conditions under which this privilege may be exercised by physicians.

It is now officially declared by the courts that "ignorance of the law," as ultimately laid down by them, "excuses no one." This rule apparently does not apply to the Government's own agents most, if not all, of whom are lawyers by profession. According to Mr. Greenfield the only remedy for a holder of a license for prescribing narcotics, for which he is taxed, is to appeal to the courts for a decision to make these rights safe to exercise or else try to have the law amended to make it clear. This is a most encouraging prospect for the medical profession of this country, the only one in the world whose government dictates to its physicians the conditions under which they may prescribe narcotics with every prospect of becoming convicted felons if they misinterpret narcotic laws which even the Government's own officials apparently do not understand.

JOHN P. DAVIN, M.D.

117 WEST SEVENTY-SIXTH STREET.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Dec. 4, 1920.

Regional Medical Staff.—A new project of the Health Ministry has been inaugurated recently. A staff of medical officers has been appointed, the object of which is to make available to insurance practitioners and to approved societies the impartial services of Government medical officers of wide experience who will advise on questions of doubt as to incapacity for work, and on cases in which undoubted incapacity is prolonged and with regard to which it is desirable to obtain a second medical opinion. Such officers have now been assigned to convenient regions in England and Wales, and will be assisted in certain of their duties by medical officers engaged to give part of their time to this work. The work of this regional staff, insofar as it directly relates to insurance practitioners, may be considered under three heads. (1) The arrangement for the examination of patients certified as incapable of work, and for reporting on the question of incapacity. (2) The arrangements for making available the advice of regional medical officers in consultation with the insurance practitioners on cases in which the question of incapacity does not necessarily arise. (3) Other duties in relation to the insurance medical officers. It is officially stated that these medical practitioners were not appointed as the result of a recent decision. In 1913 the matter was discussed by the Insurance Commissioners, the approved societies, and the medical practitioners, and it was then considered desirable to make the appointments, each one carrying a salary of £1000 a year. The subject was raised in Parliament, and in July, 1914, the payment was sanctioned. The war prevented the appointments being made, but the Ministry of Health determined a short time ago that the time had arrived for carrying out the project. It is further explained that the appointment of these officers, insofar as it affects the Insurance Act, will ultimately benefit the tax-

payer. Any saving effected will not only benefit the approved societies, but also help the exchequer, which bears two-ninths of the cost of the benefits.

Death of a Well-known French Radiographer.—Another martyrdom to science has just been reported. Dr. Infrois, Principal of the Central Laboratory of Radiography at the Salpêtrière Hospital, Paris, has fallen a victim to the x-rays. From 1898 he had devoted all his time to the practical application of the x-rays. During the past ten years he underwent twenty-two surgical operations to alleviate the injuries caused by the rays. First the fingers of his right hand had to be amputated and in course of time he lost his right arm and four fingers of his left hand. In June last his left forearm was amputated, but he still continued to work. However, a month ago his strength gave way and on November 29 he died.

The Prevention of Malaria.—A meeting of the War Section of the Royal Society of Medicine was held on November 8 last, when Major Angus MacDonald read a paper on some problems connected with malaria, with special reference to prevention. With regard to quinine, he believed that there was little, if any, evidence of the beneficent action of this drug in prophylaxis, and considered its impracticability widely demonstrated on civilians and armies. While quinine was a proved specific for treatment, it was but a sophistical aid to prevention. Knowledge of parasitology was an essential guide to prevention, and he was of the opinion that while falciparum and vivax were widely distributed the quartan parasite was very localized. The bionomics of anophelines required careful study, and he considered temperature a very important factor, malaria did not occur in any area where a mean temperature of 60° F. was not present for some period of the year. He instanced malaria in England in proof of the influence of temperature; thus, in 1917 a mean temperature of 60° was reached in June, and army returns of malaria, of which there were about 200 cases during the summer, began in July. In 1918 a mean temperature of 60° was not reached until July; the first cases were reported in August, and the total was about 80. In 1919 60° mean temperature was not reached until August; the first cases were reported in September, and there were only 40 cases. The mean temperature for plasmodial sporogony was about 60°, the maximum 90°, and the minimum probably somewhere about 50°. The relative temperature needs of falciparum, vivax, and the quartan parasite, required further study. He felt certain that temperature greatly influenced prevention. Nets and screening were the methods of personal prevention, but culicifuges were of little use. Mosquito destruction was the most important method of prevention. Col. P. H. Henderson, who took part in the discussion, looked forward to the increase of antibodies by preventive inoculation as the chief means of prevention in the future. Rear Admiral P. W. Bassett-Smith considered quinine of value as a prophylactic and instanced as evidence of this the reduction in the Italian army of from 80 to 60 per cent. and then 12 per cent. in succeeding years, according to the thoroughness with which quinine was administered. Excerpts from Major MacDonald's paper and from the discussion have been

quoted to show that the experience gained by British medical officers during the war in districts in which malaria was rampant seems to go to show that belief in the prophylactic influence of quinine on malaria is fallacious. The majority of these hold the view that quinine is of little or no use in preventing malaria and some go so far as to assert that quinine has hindered prevention rather than helped, because it is employed in place of those radical measures which are known to extirpate the disease. Destroy the malaria-bearing mosquitos and the disease will die out. Perhaps there is hardly the belief in quinine in treatment as formerly, in fact there are some who deny much therapeutic virtue in quinine in the treatment of malaria. The whole subject appears to require investigation.

Hospitals and the Rates.—In what is known as the Miscellaneous Provisions Bill, introduced by Dr. Addison, the Minister of Health, into the House of Commons recently, a clause sets out that County Councils shall have the power to supply and maintain hospitals, to contribute to voluntary hospitals within their area, to undertake the maintenance of poor law hospitals or infirmaries, and to establish ambulance services. In short, this clause gave County Councils the power to assist voluntary hospitals from the rates. This proposal met with severe opposition, and it has just been announced that Dr. Addison has intimated that he would appoint a strong, impartial independent committee of five to report promptly on the financial position of voluntary hospitals throughout Great Britain and to make constructive recommendations. In the meantime the power proposed to be given to the County Councils to contribute to such hospitals will probably be struck out of the bill. The Ministry, however, holds to its proposals to make available through the County Councils as far as possible, the 30,000 beds usually empty in hospitals controlled by Poor Law authorities. It is also announced that the "small, strong, impartial, and independent committee" is not to comprise any medical men or anyone connected with the medical profession or with hospital management. It will probably be composed of experts in finance and in local government. Presumably the idea of excluding medical men or those connected with hospital management is that the matter will be approached impartially and disinterestedly. However, it appears somewhat out of the natural order of things that a committee appointed to report, even though it be only on the financial situation of the British voluntary hospitals, should not contain a single medical or hospital representative. It is to be sincerely hoped, too, that the investigation will be made and a report issued promptly. Parliamentary committees have a way of unduly delaying their reports. In this instance it should be borne in mind that the matter is quite critically urgent in view of the present financial situation of the hospitals.

In the House of Commons on December 2 last, further consideration was given to the Ministry of Health (Miscellaneous Provisions) Bill. In view of the decision to appoint an impartial committee to inquire into the circum-

stances of voluntary hospitals Dr. Addison, Minister of Health, moved to delete the paragraph of Clause 11, which gave authority to county councils to contribute to voluntary hospitals. Deletion of the paragraph was carried.

Financial Position of the London Hospital.—It may be thought that too much attention is paid in these letters to the voluntary hospitals question. But the matter is one of such supreme importance alike to the public and the medical profession, and its discussion cannot but contain so many points of interest to American medical readers, that it would be almost a dereliction of duty not to deal with it at some length. A meeting of the Court of Governors of the London Hospital, which took place on December 1 last, gives a very good idea of the position of the voluntary hospitals in Great Britain. The London hospital is the largest in the country, is situated in the midst of the poorest district of London and has but a very small endowment. Its position was well put in an address made at the meeting by Viscount Knutsford, the President of the Court of Governors. It is recognized, he said, that a hospital without a large endowment must to a certain extent live from hand to mouth, but it is beyond reasonable possibility to expect that the income of the hospital for next year can be increased by voluntary effort to a sufficient extent to meet the estimated expenditure.

The speaker went on to say that it must not be inferred from present difficulties that the governors had any cause to regret the policy of the hospital in the past. The income from investments, trust funds, and estate was greater now than ever before, and this despite the fact that within the past twenty-five years the hospital had been rebuilt at a cost of £727,372. Up to 1914 the hospital paid its way and was able to keep abreast of the improvements in building and equipment which the advance of medical and surgical science required. At the end of that year, after an expenditure of £123,334, there was a credit balance of £9,000. In 1919 the expenditure was £221,024 and the debit balance over £65,000. This year the expenditure would probably reach £275,000, an increase due, not to any extension of work, all proposed extensions had been cancelled, but to the abnormal rise in prices and wages since the war. The estimate for expenditure next year was £300,000, and toward this they estimated their income at £150,000, leaving a deficit of £150,000. The House Committee, Viscount Knutsford said, had gone most carefully into every possible means of cutting down expenditure and were convinced that to do this to a sufficient extent would mean entirely to destroy the present standard of efficiency. To do this in regard to an institution whose work was national could not be regarded other than as a disaster, and the House Committee felt strongly that the time had come when, at any rate for hospitals in the category of training, and research centers, such as the London hospital, some aid should be forthcoming from the State to supplement voluntary charity. The chairman, however, allowed that by advocating State or municipal aid, a good deal of controversy had been raised.

Phrases like "the death of the voluntary system" had been freely used. The committee would assure the governors that they desired as strongly as possible the retention of the voluntary system in its essentials. There were some who would cling to a voluntary system pure and simple, however inefficient the service which might result. Such ardent partisans generally overlooked the fact that the majority of the larger hospitals were already receiving State aid in some form or other. Therefore in advocating such aid they were only asking for the extension of a principle which had long since been accepted. The speaker declared that there was no ground for supposing that the receipt of State aid would kill voluntary charity. Medical and surgical science, and the various forms of treatment, grew daily more complex, and the committee felt that the point had been reached when an efficient hospital service could not be carried out by voluntary charity, alone and unaided. Referring to the committee appointed by Dr. Addison to inquire into the position of voluntary hospitals, Lord Knutsford said the future of the London hospital would seem largely to depend on the recommendation and findings of that committee.

Most of Lord Knutsford's address has been quoted, not only because as said before the London Hospital is the most conspicuous example in Great Britain of a voluntary hospital almost wholly dependent on charity, but also because Lord Knutsford is the most competent and successful hospital manager in the country. He is an authority whose words carry the greatest weight and when he declares for State aid or partial State aid all will listen to him with close attention. And yet the majority of the public probably, and the greater part of the medical profession certainly, are strongly opposed to nationalization of the hospitals in any form. However, another notable authority, Sir Napier Burnett, believes that the problem can be solved by proper organization and by the introduction of modern business principles into the management of the hospitals.

The London hospitals in particular in the past have relied nearly wholly upon spasmodic appeals for funds. This method has failed. The public should be taught the value in crude cash of the hospital to the community and a definite appeal should be made to all the various beneficiaries. Especially are such benefits evident in the case of insurance companies who practically contribute nothing. Employers of labor do not contribute in proportion to their means and employees as a rule give very little. It is left to the already overburdened middle class people largely to support institutions from which they receive no benefits. Why then should not a pay system or partial pay system be introduced? Under this system all who require and ask for hospital treatment would pay according to their means and the hospitals might be continued on the voluntary basis. The inquiry into the financial condition of the hospitals should result in the situation being made clear. Then adequate steps could be taken to reorganize them. At present it is a matter, to a great extent, of groping in the dark.

4. Malignant Disease of the Kidney with Unusual Symptoms. J. Deinger Barney.
5. Report of a Case of Acute Encephalomyelitis with Autopsy. Howard Osgood.

1. The Differential Diagnosis of Tuberculosis.—E. O. Otis discusses the following conditions which may be mistaken for pulmonary tuberculosis: Diseases of the upper respiratory tract; pulmonary diseases; influenza, collapse; bronchitis, asthma; bronchiectasis; emphysema, abscess, gangrene; cardiac lesions; diseases of the pleura; cancer of the lungs; actinomycosis; aortic aneurysm; syphilis of the lungs; anemia, neurasthenia, dyspepsia, anorexia; hyperthyroidism. In order to view the question of the differential diagnosis of tuberculosis from another angle he enumerates the various causes of blood-spitting; pulmonary tuberculosis; lesions of the upper respiratory tract, epistaxis, gums, varices; gastric ulcer; mitral stenosis; infarcts from emboli; aneurysm of aorta; bronchiectasis; abscess or gangrene of lungs; influenza; asthma, emphysema, bronchitis; from esophagus, cirrhosis of liver; acute specific fevers; cancer; arthritis; from unknown cause. Attention is called to certain sounds sometimes heard on auscultation which more or less resemble râles and which may mislead the examiner, but which arise from other causes and are not due to any pulmonary disease. He enumerates these as follows: (1) So-called "marginal sounds," closely simulating fine râles and heard in the lower axilla, especially the right, and only on inspiration; they are caused by the separation of the pleural surfaces as the edge of the lung penetrates into the complementary space. (2) Muscle and joint sound, heard over the sternum, in the vicinity of the sternocostal articulation; also along the clavicle and in many cases over the apices, the sounds being transmitted from the shoulder-joint and the sternoclavicular joints. (3) Atelectatic râles, heard at the first deep breath or cough and not repeated, generally considered to be caused by the forced opening of atelectatic alveoli. (4) Slight dullness or rise of pitch at the right apex, with harsh or bronchovesicular respiration, heard especially above the clavicle anteriorly and to the third dorsal vertebra posteriorly with increased voice sounds is physiological and not pathological for the right apex.

3. The Use of Atropine in the Treatment of the Hypertonic Infant.—Albert D. Kaiser reports these cases and summarizes his views as follows: The hypertonic infant presents a definite clinical picture, due to a disturbance of the autonomic nervous system which gives rise to physical and psychic disturbances. The usual manifestations are irregular vomiting often with visible peristalsis, constipation, malnutrition, muscular irritability, representing the physical defects, and with insomnia and crying as psychic disturbances. The diet usually needs no change in the hypertonic infant and the food is well digested. Atropine gives early relief of symptoms and thereby metabolism is increased, bringing about the desired gain in weight. The use of the atropine is not dangerous if given in guarded doses and the early toxic symptoms are noted.

5. Six Months' Experience with a Nutrition Class.—Louis M. Ruderman bases this report on the work in connection with the nutrition class of the Brooklyn Hospital. Membership in the class was limited to children of school and kindergarten age, 5 per cent. or more under weight. Intensive work was carried on with fifty children, during a period of six months. While these fifty children are still below par in state of nutrition, considerable improvement has been shown during the period of the work, being now only 5.5 per cent. under weight. Attention is directed to the fact that these children came to the class on account of poor nutritional status. They were apparently raised to a nutritional level, where they are accomplishing what is expected of a normal child in this regard. The writer emphasizes the importance of gaining the child's confidence. He believes that if similar work were undertaken in every congested district of the large cities it would greatly contribute toward making stronger men and women and better citizens.

9. Empyema in Children.—Elizabeth Glenn bases this study on the statistics of the Children's Service of the University Hospital since 1907. There were discharged cured, 24; discharged, improved, 28; died, 12; total, 64. The length of stay in the hospital, under one month, 22; under two months, 24; over two months, 6. The mortality in these children, all of whom were under twelve years of age, was only 18.7 per cent., while the average adult mortality ranges from 20 per cent. up. The writer warns that conclusions must be drawn cautiously, but considers it safe to conclude the following: (1) The incidence in males is greater than in females. (2) The left side is more often involved than the right. (3) If the mortality rate for empyema in children under one year is excluded, the death rate is lower in children than in adults. (4) In children under one year the mortality in our six cases was 66.6 per cent., instead of the 90 to 100 per cent. usually given. (5) In the postpneumonic empyemas, when the patient was operated on within the first week after onset, the average stay in the hospital was shorter and the proportion of cures higher than in those operated on at a later time.

4. The Therapy of Catarrhal Fevers.—Bernard Fantus, under the head of etiopathic therapy, states that the best prophylactic against endemic catarrhal fever, or "colds," is "hardening," i.e., accustoming the body to exposure to cold, so that such exposures do not produce chilling. The very young, the very old, and those crippled by organic disease, may be harmed instead of benefited by the hardening process. For these, protection by suitable climate or by keeping indoors during inclement weather, is a rule of safety. Removal of chronically inflamed tonsils, adenoids, or nasal polypi, straightening of deflected septums—in short, doing away with foci of infection—is an important principle of prophylaxis. Prophylactic vaccination is at best an experiment in any case. It may result in benefit or in harm, dependent on a number of conditions, some of which are at present not under control. Under the head of restorative treatment, the

writer considers that the chief problem in catarrhal fever is to restore the lost immunity. To favor this, the single most important item known is warmth, just as chilling is, no doubt, an important factor in the loss of resistance in many cases. As long as the patient's temperature is normal confinement in adequately heated rooms might be sufficient; but when the heat-regulating mechanism has been upset to the degree evidenced by fever—no matter how mild—absolute rest in bed is imperative. Diaphoresis by means of heat is a time-honored remedy, the more efficient the earlier it is used. Alkali is the only medicament likely to aid in the establishment of immunity. There is some evidence that acidosis is present in these fever patients, and that acidosis antagonizes immunization. There is also a clinical tradition that alkali favors recovery and prevents complications, perhaps by antagonizing acidosis. Sodium citrate is the most pleasant administration form of alkali. A glassful of lemonade every two hours, to which a quarter of a teaspoonful of baking soda has been added, may be recommended. Or one may prescribe 1 or 2 gm. of sodium citrate in lemon or orange syrup, to be taken diluted with a glassful of water every two hours. The liberal—though not excessive—use of fluids is important in all cases. From one-half to one tumblerful should be given every hour while the patient is awake. It may be prescribed in the form of liquid diet, given every two hours, and a fruit drink every two hours, alternating with the liquid diet. Of course, if there is albumin in the urine, soup and other preparations derived from meat would be interdicted. Hyperemia-producing agencies must not be employed in the presence of extreme congestion. At such time only cleansing and soothing or astringent applications are admissible. Under the head of symptomatic treatment, among other recommendations, the writer states that cathartics need not and should not be given in a routine manner. Having employed calomel-saline catharsis up to within the last few years, and having reaped a few cases of stomatitis as the result, he has practically given up the practice, and finds that his patients are none the worse for the change. The early administration of saline or castor oil is either responsible for or at least coincides remarkably often with initial vomiting, which continues sometimes as the most annoying part of the clinical picture. If the patient's bowels have not moved for twenty-four hours the administration of an enema of 2 per cent. baking soda does no harm, and usually accomplishes all that is desired. If not, magnesia magma may be given every two hours, a teaspoonful or two for infants, a tablespoonful or two for adults, until a satisfactory evacuation is secured. If this does not act well, a peristaltic stimulant, such as cascara sagrada, is required. Of the aromatic fluid extract of which a teaspoonful or more may be given. Summing up the question, the following points are emphasized: To draw a sharp distinction between influenza, grip and "colds" is futile; hence the term "catarrhal fevers" is advocated to embrace the whole group. The recognition of the essential similarity of these conditions might enable us to turn our experience with influenza to good account in the treatment of the common "cold." Even a mild case of catarrhal fever requires absolute bed treatment, continued until the patient has been well for several days. "Coddling" is the rule of safety in catarrhal fever; "hardening" in its prophylaxis. With the possible exception of alkalis, the use of medicines is merely symptomatic. We must beware against procuring comfort by the sacrifice of interests more vital to the patient. Thus, routine antipyresis is a mistake, though the sparing initial use of a few small doses of members of the antipyrin or salicylate group as analgesics may do no harm. Opiates to check cough should be used most exceptionally in catarrhal fever. The indication is to favor expectoration, as by saline expectorants and by fluid.

10. Paraffinoma and Wax Cancer.—Benjamin Franklin Davis reports a case, and discusses the clinical pathology of skin lesions from prolonged exposure to paraffin. Paraffinoma may be said to be a chronic granuloma produced by prolonged, continuous exposure of susceptible tissues to the irritation of paraffin. Disfigurement, deformity and interference with function, if the lesion is in a region requiring motility, are the

chief types of disability resulting; cancerous degeneration, "wax cancer," is an occasional intruder. Complete extirpation of the involved tissue is the treatment of choice. Paraffinoma probably is not the expression of a specific growth-inciting property of paraffin, but is rather the result of the long continued action of a low grade chemical irritant.

2. **Acute Rheumatism in Children Under Twelve Years of Age.**—Poynton, Paterson, and Spence record the results of a study at the Hospital for Sick Children, Great Ormond Street, of a severe outbreak of acute rheumatism in children under twelve years of age, which occurred between July, 1919, and June, 1920. They do not concern themselves here with the pathology or the treatment of rheumatism, nor do they enter upon the vexed questions that present themselves in a complete study of the disease. The total number of cases was 172, of which 84 were first attacks. A hundred and four were females and sixty-eight males, a proportion of about three to two. From the analysis of these cases the writers consider beyond dispute the extreme gravity of rheumatism in children of the class that are treated in hospitals—a fact all the more striking when one realizes how comparatively infrequent such cases are in children of the more fortunate. For those who are acquainted with the work done by the New York Association for the Prevention and Relief of Heart Disease, the absence of organized effort in England for control of rheumatism and its heart disease, they hold, is a matter of profound regret.

5. **The Disappearance of a Mediastinal Malignant Neoplasm under X-Ray and Radium Treatment.**—R. T. Lewis describes the case of a man who appeared to be suffering from neoplasm of the mediastinum, but who, under the influence of x-rays and radium, seemed to lose some of the signs and symptoms of the disease. On clinical grounds there was reason to believe that just as the cervical gland had disappeared in this case on three separate occasions previously under the influence of x-rays and radium, so now on this fourth occasion one had disappeared as well as the axillary glands under similar treatment. It is assumed that the dullness of the left chest was due, in part or wholly, to infiltration of the lung by the malignant growth, and that this infiltration not only involved the sympathetic and left recurrent laryngeal nerves, but also caused venous and lymphatic obstruction over the upper left arm and chest, and caused enlargement of the veins of the chest wall. The disappearance of the dullness of the left chest under x-rays and radium harmonizes with the view that the infiltration of the lung by malignant growth had been overcome, hence the relief from some of the signs and symptoms. An obvious objection to this view must be raised because it is conceivable that the dullness to percussion of the left chest and the x-ray appearance were entirely due to a large pleural effusion, and that it is the resorption of this pleural effusion which led to the improvement of signs and symptoms, the pleural effusion, the dropsy of the chest wall, and the enlarged veins being all due to thrombosis of the innominate veins and their branches, and that the recovery from this thrombosis and not the disappearance of the malignant growth is the cause of the present happy result. In answer to this objection the writer states that the heart never has been dislocated as much as it should have been had the left chest been full of fluid from the top to the bottom; that it is not a feature of blockage of the large veins of the neck occurring in mediastinal neoplasm to pass off, either spontaneously or as the result of x-ray and radium treatment; that in such blockage of the veins with re-

sulting edema and pleural effusion the obstruction is generally due to direct invasion of the vessels by the neoplasm and its terminal. It seems to him probable, therefore, that x-rays and radium have directly checked the growth and even caused retrogression of the mediastinal neoplasm in the case reported.

3. **Removal of Adenoids in Infancy.**—Hunter Tod reminds one that no topic can possibly have been treated more exhaustively than that of adenoids, but in spite of the plethora of papers on this subject very little has been mentioned with regard to adenoids in infants (babes under nine months old). It is common knowledge, or should be, that the healthy new-born infant after crying lustily soon subsides into a peaceful sleep. Who has ever seen a new-born babe lying asleep with its mouth open? Subconsciously it keeps the mouth closed, so that nasal obstruction from any cause will give rise to imperfect respiration, perhaps sufficient to cause cyanosis and to simulate laryngeal obstruction. These babes if left unaided may quickly die. Three conditions are possible causes of such a contingency: (1) swelling of the nasal mucous membrane and the presence of mucous secretion; (2) congenital obstruction of the nasal cavities or of the posterior nares; (3) adenoids. A weak solution of adrenalin chloride sprayed into the nasal cavities suffices in the first and commonest cause of obstruction. The second is external, rare, judging from the writer's experience and literature, perhaps because the infant in such cases succumbs before the condition is recognized. Adenoids, when present at birth, are never sufficiently large to endanger the child's life. At the same time they may give rise to obstructed nasal breathing, shown by restlessness, in-drawing of the diaphragm, and inability to suck. A few days after birth the infant begins to breathe with the mouth open, to snort and sniffle. Owing to the nasal obstruction it swallows air while trying to suck, which makes it sick and gives it windy spasms. If, owing to consequent dyspeptic troubles, the infant gets a rash, the doctor may suspect congenital syphilis. Adenoids, present at birth, give rise to immediate symptoms; congenital syphilis about the third week. When removing adenoids under the age of six months, especially if the baby be undersized or ill-developed, a general anesthetic is neither required nor advisable. The infant is held in a sitting position by a nurse, a small curette is passed up behind the soft palate into the post nasal space and brought down with one sweep. Owing to the small size of the post-nasal space, it requires but a tiny pad of adenoids to give rise to symptoms, but in some cases one is surprised at the amount of adenoids removed. As a rule, very little bleeding takes place, and there is rarely any shock, but the infant should be kept warm, and, if there appears to be any shocks, should be given a drop or two of brandy in a little milk. It is advisable not to feed the infant for three hours before the operation takes place, so that it can be given the breast or bottle within ten minutes or so after the operation has taken place. The writer strongly urges that adenoids should be removed whenever they give rise to any symptoms which may adversely affect the child's future welfare.

5. **Renal Complications of Acute Lacunar Tonsillitis.**—H. L. Cronk, from a study of the subject, reaches the following conclusions: 1. Albuminuria is very common in acute lacunar tonsillitis. 2. This albuminuria is not always of the simple febrile type. 3. True febrile albuminuria does occur in some diseases such as influenza. 4. Nephritis occurs in a small but not negligible number of cases of tonsillitis; it is of the latent variety with few signs. 5. The nephritis of lacunar tonsillitis is similar to scarlatina in its tendencies to recovery.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Seventieth Annual Session, Held at Pittsburgh, October 4, 5, 6 and 7, 1920.

GENERAL MEETING.

THE PRESIDENT, DR. HENRY D. JUMP, IN THE CHAIR.

President's Address.—Dr. HENRY D. JUMP of Philadelphia delivered this address saying that year after year advocates of unique forms of treatment had asked for state registration. It had been our duty to contend against these for the public must be protected against improperly educated practitioners. There should be uniform requirements of knowledge in the fundamentals for all who practised the healing art. There was a growing tendency to place medical treatment under State supervision; that physicians should be under salary and assigned to districts in which to practise. Such a provision would not be desired by the profession. The fees offered under the Workman's Compensation Act were smaller than those prevailing for similar service rendered privately and physicians should refuse to accept work at rates which were below those being established by various County Societies. We were justified from the standpoint of the people and the good of our own profession in resisting efforts to establish Compulsory Health Insurance in this State.

The Physician and the Public Schools.—Dr. THOMAS E. FINEGAN of Harrisburg presented this paper in which he stated that the function of the school was no longer regarded as that simply of a class room. A public school, wherever it was maintained in America, was an institution which was to serve every intellectual necessity of the people who maintained that school. We were not content, therefore, in teaching children the usual subjects which had been put in the curriculum, but one of the first and most essential things to be given consideration was the health of the child. Parents and children had no control over the matter of attendance at school. Therefore the children should be protected in every way when they were placed in school. If we were going to give instruction upon health it must be upon the right basis and we must have a syllabus upon health. He said that there were three men, whom he regarded as the leading experts in the country, at work on this subject and they were going to have in a very short time a syllabus worked out which would begin with the child when that child entered school and would go through the eight years of elementary school course and the four years of the secondary school course.

Dr. EDWARD MARTIN of Harrisburg said that in this great work, the most splendid and profitable work in which any one could engage, every one of the profession was a worker. The State Department of Health was their department. The executive officers of the State Department regarded every member of the medical professions as one of its active working, efficient forces. There could be no antagonism between that Department and the doctors, there could be only co-operation. As far as the doctor's private capacity was concerned, exactly as the State Department became more efficient the doctor's individual standing was bettered.

The Outlook of Chronic Nephritis.—Dr. JAMES M. ANDERS of Philadelphia read this paper in which he said that the rules of renal function in disease were not hard and fast. The classification of cases of chronic nephritis was imperfect. There were many atypical cases probably due to previous infections. The outlook in these cases was modified by the extent of fibrosis; when this was limited, life might not be shortened. Many of the arterial hypertension cases had endured for many years without appreciably deteriorating. Cases of cyanotic kidney due to cardiac disease showing albumin and casts cleared up quickly when the heart improved. The prognosis in confirmed chronic parenchymatous nephritis was exceedingly grave though not altogether hopeless. In the interstitial cases the outlook was at times guardedly favorable if recognized early.

Dr. M. H. FUSSELL of Philadelphia said that the recognition of some infection which was causative of nephritis would frequently prevent the dire results of a kidney lesion. It seemed to him true that the loss of function in chronic nephritis was made distinctly more dangerous by the thoughtless use of so-called diuretics. It must be borne in mind that casts and albumin did not mean the death warrant and their presence might be of no importance as to longevity. The functional tests were valuable both in prognosis and treatment.

The Health of a Community.—Dr. JOHN D. MCLEAN of Harrisburg presented this paper in which it was stated that by a union of the medical care of a community with the powers of the State Department of Health was brought about a lessening in the number of persons suffering from diseases. The accomplishments of a community were measured by its health and the health of the community was measured by the training and activities of the doctors of that community. He wanted to plead with the doctors to maintain the health of their community, especially if they had a rural district, by reporting their cases of typhoid fever at once, even if they were only reasonably suspicious that it was typhoid fever. Two epidemics had only recently been traced to the milk on a milk producing farm.

Dr. ROBERT A. KELTY of Danville wished to direct attention to the work being done by Col. Martin and Col. McLean through the State, and when these men showed the doctors what to do they were the ones to do it. Col. McLean had spoken of typhoid fever and he could tell of an epidemic where 29 cases had materialized following the infecting of the water supply of a town of 7000. It was up to the doctors to protect that water supply. It was up to each one in his community to correlate with the State Department of Health.

Dr. THOMAS M. STAHLMAN of Pittsburgh said that it seemed to him that what was badly needed in rural communities was isolation hospitals. Where treatment could not be carried out at home these cases should be sent to these isolation hospitals. One thing which impressed him in rural communities was the unsanitary condition of school buildings.

End Results in 534 Cases of Peripheral Nerve Injuries.—Drs. W. WAYNE BABCOCK and JOHN O. BOWER of Wyncote presented this paper which they said contained a tabulation of operations for nerve injuries in 608 cases. Operative exploration of nerves was harmless and usually helpful in the milder forms of injury. Results were much better in operative than in nonoperative treatment. Nerve grafting and lateral implantation gave poor results and were rarely necessary. Accurate end-to-end suture was possible in nearly every case despite long gaps. Regeneration was almost invariable after suture. The rate of regeneration was about one inch a month, the small muscles of the hand were the last to recover. If nerve function had not been restored within 3 months after healing of an injury nerve suture should be resorted to.

Dr. CHARLES H. FRAZIER of Philadelphia said that according to the experience of European surgeons early in the war there was only one operation which need be considered in any case of peripheral nerve injury with complete anatomical nerve block, that was the end-to-end suture. The power of regeneration in the peripheral nerve was very extraordinary and quite as active as the process of repair and regeneration in other tissues. The peripheral nerve received its blood supply from minute blood vessels throughout its entire extent and if the nerve was completely isolated for 12 or 15 cm. and cut free altogether from a large portion of its arterial supply, the likelihood of arterial regeneration for complete restoration of function were not great. Another point which should be borne in mind and always was to get freedom from scar tissue. The more nearly we reapproximated the nerve according to its original condition the greater was the likelihood of restoration of function.

A New Concept Relative to the Treatment of Malignant Disease.—Dr. WILLIAM L. CLARK of Philadelphia read this paper stating that excision or other treatment of a primary malignant lesion, and block dissection of metastatic glands was not sufficient. Migratory cells in lymphatic ducts must also be taken into considera-

tion, else they would drain into the tissues after the glands were removed, and rapid progress of the disease usually resulted. Lethal action of radium on malignant cells of all types had been proved in laboratory and in practice. At least one maximum radium treatment with accurate technic was advocated, preparatory to any other procedure, for the purpose of rendering benign the migratory cells in the ducts, and to wall off glands with fibrous tissue. At least three radium treatments, averaging six weeks apart, should also follow any operative procedure. The folly of depending on operative surgery, or other methods alone, in cancer with metastasis, and the wisdom of ante- and post-operative radium treatment was amply demonstrated by clinical evidence. The invaded glands not broken down would usually disappear under radium treatment and excision would not be necessary. If degenerated in the interior, they would not disappear, but radium treatment would convert the capsule into benign fibrous tissue. Then the gland might be incised and drained with safety. Hollow, non-corrosive, steel needles, containing radium salts representing a known quantity of radium element, inserted into malignant growths and glands, produced results that could not be produced by radium applied from the outside in capsules or plaques. The judicious combined use of operative surgery, electrothermic methods, radium, and the roentgen ray would often clinically cure even very advanced and inoperable cases of carcinoma and sarcoma.

Dr. G. BETTON MASSEY of Philadelphia said that he did not see how the radium rays were so much more effective than x-rays when properly applied and it was possible that some of the bad odor of the x-ray treatment of cancer was due to a lack of use of the proper remedy at the proper time. That was, the lack of use of several remedies, the association of remedies, the knife possibly in some cases, but more particularly the electrothermic method which got rid of the bulk of the accessible growth before the x-ray was applied. It appeared to him that the x-ray had a special field in the subdermic diffusions. He had cases that were well at the end of 17 to 20 years from this electrothermic treatment, or, as it was then called, cataphoric destruction.

Dr. RUSSELL H. BOGGS of Pittsburgh said that he agreed with all Dr. Clark had said. It was folly to depend upon the cautery or surgery in the treatment of cancer without ante- and post-operative treatment. It must be remembered that the lethal dose for most types of cancer was from three to six times the erythema dose. Lip cancers were probably more successfully treated by applying radium to the lip and radium and x-rays to the adjacent glands than by the most extensive surgical operation which cut out the center of the growth and only hastened metastasis. The most extensive glandular dissection was seldom successful.

Obstetrics and the General Practitioner.—Dr. J. WHITRIDGE WILLIAMS of Baltimore read this paper saying that many specialists tended to overlook the fact that at least 80 per cent. of all deliveries had to be conducted by the family physician or by a midwife and that the services of specialists were available only in large cities and towns. Expert knowledge of the niceties of pelvimetry could not be expected of the average practitioner; all that could fairly be demanded was that he so treat his patients that they might be reasonably assured of a successful outcome, and the recognition of gross deformities. The patient should be taught to engage his services at an early period of pregnancy, that she might be assured of reasonable prenatal care, and all that it implied, particularly in reducing infant mortality during the first year of life. Patients with gross pelvic deformity, as well as those in whom unrecognized disproportion had led to disastrous results in the past, should be sent to specialists for expert advice. Dublin had shown that of all maternal deaths in this country 45 per cent. were due to infection, 26 per cent. to various forms of toxemia, while the remaining were due to other causes combined such as dystocia, hemorrhage, etc. Attention should be directed especially toward diminution of mortality from the first two causes. The remedies were aseptic technic and the greatest possible restriction of vaginal

examination, which should be replaced by abdominal palpation and rectal examination.

Dr. BARTON COOKE HIRST of Philadelphia said that there was a great future for the reduction of morbidity in women after childbirth. It was possible for the physician to cut off 61 per cent. of all diseases of women by attention to two factors: the repair of injuries and the prevention of retroversion. One could repair the injuries of childbirth immediately after delivery. By making formal intermediate operation all the injuries could be repaired. Postural treatment during the puerperium would reduce displacements to about 3 per cent.

Dr. WILLIAM N. BRADLEY of Philadelphia said that in his work at the Starr Center in Philadelphia he had had under his care during the past year 252 cases of pregnancy. Of this number, 131 had been delivered. Of the 131 there were two abortions and one premature labor with a living baby. He was happy to say to Dr. Williams that the entire number of 128 babies were being breast fed at the end of one month, which was an important point from the pediatric standpoint. As to early consultation of the physician by pregnant women, the importance of this could be overestimated. He found in the class of women he had to deal with that the blood pressure during pregnancy rarely exceeded an average of 105. This same group of women 3 months after delivery had a blood pressure of 115 or 120. One should not go to the extreme of underfeeding these women in pregnancy in order that they might have a delivery free from danger.

Dr. PAUL TITUS of Pittsburgh said that he had found that students who were on duty only 18 days became proficient in rectal examination and were able to avoid a large number of vaginal examinations. This was overlooked by the general practitioner. A man might become proficient in the rectal examination in a very short time. As regards the immediate repair of the perineum, with all respect to Dr. Hirst he differed with him. Certainly it did no harm to attempt repair. He believed a certain amount of granulating suppurating surface was avoided by the closure of the perineum immediately after the birth of the child.

Dr. J. WHITRIDGE WILLIAMS of Baltimore said puerperal infection in the hands of the profession at large in this country caused as many deaths now as it did 30 years ago. That was not his statement, but he had gotten it from reading statistics. The consequence was that there was radical need of prevention of vaginal examination.

Is the Practice of Medicine Worth While?—Dr. EVAN O'NEILL KANE of Kane, Pa., read this paper saying that the physician's viewpoint was that the practice of medicine was worth while, though realizing its strenuousness. It was peculiarly attractive and afforded especial opportunities to enter upon political and public careers. A deep knowledge of human nature was afforded; scientific study; many friends; few physicians abandoned practice when fully engaged. It was a life which tended toward compassionate regard for his fellow, through continual contemplation of suffering and forced self-denial for their relief, changing the most mercenary of practitioners, in time, unconsciously into a philanthropist; loving his art he became a lover of humanity. Gratitude was an insufficient reward. The long and expensive curriculum discouraged aspirants. Physicians' fees were inadequate. The medical profession should seek a remedy.

Dr. JAMES JOHNSTON of Bradford said that of all men the physician was closest to all that was real and vital; closest to the coming and going of humanity. Theirs was the work that was most appreciated.

Dr. SPENCER M. FREE of Dubois said that if your ideas in life were money, ease, fame, love of your fellowman to the extent of praise, if you wanted to have a good time, if you wanted to be in society, if you wanted to marry a woman and make her happy instead of uncomfortable and miserable, then you should keep out of medicine. If you want to live the ideal life, if you had that in your soul which fixed your eye upon the stars if you had in mind the great Man of Nazareth and did not care for the accumulation of money and did not mind to miss a meal from time to time, did not mind what people said about you, then you should choose medicine.

Altered Blood Pressure as a Manifestation of Imbal-

ance.—Dr. DANIEL J. MCCARTHY of Philadelphia read this paper, stating that any fault in any one of the important endocrine glandular structures led to an essential fault in the blood pressure mechanism and any fault here led to serious damage to the developing brain and nervous system. A common cause of this condition in children was tuberculosis in the parent. As the child grew to manhood the increased mental reflexes gave a hypersensitive individual with a tendency to introspection and dissociation of personality. In this group of cases adolescent insanity was not infrequently seen.

The Industrial Physician.—Dr. J. WESLEY ELLENBERGER of Harrisburg read this paper saying that since 1916 the industrial physician had been a factor of real importance. His duties included examination of every prospective employee with reference to the family physician or specialist according to his needs; looking after those injured; counseling with those who were ill; caring for working conditions of the employees; inspection of the plant; education of the employees in health matters. His efforts also contributed largely to the success of the plant employing him.

JOINT MEETING WITH THE INTERSTATE ASSOCIATION OF ANESTHETISTS AND THE NATIONAL ANESTHESIA RESEARCH SOCIETY.

Blood Pressure Guides in Anesthesia and Surgery.—Dr. ALBERT H. MILLER of Providence, R. I., read this paper saying that despite opinions to the contrary a working definition of the condition of surgical shock could be made and followed. The blood pressure was our most certain guide to the condition of the circulatory system. Most of the fatalities attributed to surgical shock were due to factors other than surgical traumatism which, if understood, might be controlled.

Dr. E. I. MCKESSON of Toledo, Ohio, said that it seemed incredible that such a valuable guide and aid to both surgeon and anesthetist in his work as blood pressure observations should have been neglected. There were many factors which influenced the blood pressure and one who was interpreting blood pressure changes in a surgical operation must be keen, he must be watchful, he must be knowing what the anesthetist was doing from the anesthetic standpoint, he must know what the surgeon was doing and must have a clear conception of the patient in order to properly locate causes of depression.

Dr. F. H. MCMEEHAN of Avon Lake, Ohio, said that in behalf of the National Anesthesia Research Society he should like to inform those in attendance of the existence of a new uniform anesthesia record which had been drawn up by a special committee of experts to assist all those who wished to protect their patients under anesthesia with blood pressure guides.

Third Stage Ether Anesthesia—A Subclassification Regarding the Significance of the Position and Movements of the Eyeball.—Dr. ARTHUR E. GUEDEL of Indianapolis read this paper in which he made a plea for higher and better anesthesia and for better teaching of anesthesia in our medical schools and hospitals. As long as we noted any movement or eccentric position of the eyeball, aside from that which might be normal for the occasional patient, that patient had not had too much anesthetic; but after anesthesia had been well inaugurated, he had had quite enough. The upper part of the third stage, namely, the first stratum, was anesthesia entirely as satisfactory to the surgeon as the second, third or fourth stratum of the third stage.

The Anesthetic Problem in Lung Surgery.—Dr. JAMES T. GWATHMEY of New York City read this paper saying that nitrous oxide and oxygen were preferable to ether and air. A larger amount of oxygen could be given if preceded by an average in adults of $\frac{1}{2}$ grain of morphin. Positive pressure of 7 to 10 mm. of mercury must be maintained in the rubber bag. With this method first-stage anesthesia was kept up throughout as indicated by pink color, active lid reflex and rolling eye. The patient should not become cyanosed at any time.

Dr. JOHN R. MCCURDY of Pittsburgh said that he would emphasize the importance of the morphinization of the patient before any procedure is begun. Three-

eighths of a grain of morphine administered in divided doses, as Dr. Gwathmey has advised, was not a dangerous dose in these cases. The morphia undoubtedly produced a much better respiratory condition, moreover, it gave the patient comfort and relief from pain irrespective of the anesthetic agent administered; that was not only humane, but assisted very materially both the anesthetist and the surgeon.

Dr. REA PROCTOR MCGEE of Pittsburgh said that Dr. Gwathmey had given these anesthetics during the war for the most extensive chest surgery that had been done in modern times. He had given the anesthetic day after day in St. Mihiel and the Argonne, in a hospital that received non-portable casualties and in every instance his patients had seemed to sleep easily and to stand the operation with the very best results. In fact, when Major Yates made his report upon the very low death rate that he had had with his chest operations it took a good deal of faith for many surgeons to believe that the work could be done so well, but he thought that Dr. Gwathmey deserved a very large share of praise for what was accomplished in saving the lives of wounded soldiers with chest injuries.

Dr. E. I. MCKESSON of Toledo, Ohio, said that he agreed not only heartily but vigorously with Dr. Gwathmey's idea of maintaining a very light anesthesia in lung surgery. There is no necessity he knew of for maintaining a deep anesthesia. In fact he thought it was quite distinctly more dangerous to do so. A gaseous dose of morphin was of more value to the patient than the damage it might possibly do by lowering the blood pressure.

Dr. F. H. MCMEEHAN of Avon Lake, Ohio, said the papers of Dr. Guedel and Dr. Gwathmey were based on research work that had been conducted in the midst of strenuous campaigning in war. When this meeting was scheduled the National Research Society offered a series of prizes for the best papers that would be presented on research subjects. He would like to inform the Society that the Committee on Prize Award had awarded a prize to Dr. Guedel, his paper being based on 10,000 anesthetics administered in France, and a second prize had been awarded to Dr. James T. Gwathmey for his wonderful work in lung surgery, which Yates, of Milwaukee, said had reduced the mortality to practically one-third or less than what it had been before Dr. Gwathmey arrived upon the scene of action.

Nitrous Oxide-Oxygen Anesthesia for Tonsil and Sinus Surgery in the Forward Inclined Sitting Posture.—Dr. IRA O. DENMAN of Toledo, Ohio, read this paper saying that for the last 10 years he had used this position exclusively in his work, believing that it was the safest position for oral or sinus surgery. The field of operation was kept clean and free from blood and other fluids and irrigation was facilitated if needed. Inspiration of blood or infected material was avoided. With this position any procedure could be carried out under general anesthesia with nitrous oxide and oxygen.

Dr. E. I. MCKESSON of Toledo, Ohio, said that he had administered a great many anesthetics for tonsil work with the various forms of anesthesia during the past years, but none had given him the pleasure and the confidence and the control of the patient that nitrous oxide had done, particularly in this position. He had been very much excited several times in trying to resuscitate a patient who had inhaled a pharynx full of blood. So, if there was nothing else to recommend the forward inclined posture, this was quite sufficient.

SECTION ON SURGERY.

THE CHAIRMAN, DR. T. TURNER THOMAS OF PHILADELPHIA, IN THE CHAIR.

Chairman's Address.—Dr. T. TURNER THOMAS of Philadelphia made this address saying that for the past 30 or 40 years the surgeon had tended to ignore the value of a knowledge of gross anatomy which had previously been held indispensable. The pendulum seemed to be swinging backward and the medical schools were giving more emphasis to the application of anatomy to the practice of medicine, especially surgery. The late G. G. Davis had done a very important work in this direction which deserved more credit than it had yet received.

Rectal Drainage for Pelvic Abscess.—Dr. ROBERT H. ENTWISLE of Pittsburgh read this paper saying that the drainage of a pelvic abscess through the anterior wall of the rectum was not meant as a substitute in any way for the accepted approach through the abdominal wall but was reserved for those cases which did not do well following operation and in which there was found a large bulging mass in the pelvis which obviously was not draining through the original incision. The operation was very simple. The results were very gratifying.

Abdominal Drainage.—Dr. ARTHUR E. CROW of Uniontown read this paper saying that it seemed to him little, if any, danger could come from the establishment of drainage in all border line cases in removal of the gall-bladder. Too often the abdomen was closed and the mistake closed with it when drainage would have saved the day. This happened more often in appendicitis than in any other abdominal trouble. Any penetrating wound of the abdomen certainly demanded immediate operation and drainage.

The Diagnosis of Chronic Appendicitis. Its Relation to an Enlarged Cecum.—Dr. RICHARD J. BEHAN of Pittsburgh read this paper saying that chronic infection in the appendix was frequently secondary to pericecal and periappendiceal adhesions rather than the result of such infection. The symptoms were those arising from dilatation of the bowel which in turn interfered with neighboring organs; those resulting from toxic material and those resulting from stimuli reflected to adjacent organs. These were pain or discomfort in the right iliac region, constipation; in the toxic types pains in the limbs, thyroid enlargement, slight fever, rapid pulse, headache, exhaustion. In some cases heartburn, vomiting and palpitation.

Appendicitis in Children with a Report of Five Hundred Cases.—Drs. EMORY G. ALEXANDER and WALTER B. MCKINNEY of Philadelphia presented this paper saying that in this series the ages ran from 19 months to 15 years. The symptoms were more marked than in the adult. Diagnosis was more difficult as history and examination were less definite. Peritonitis was frequent as a complication. Rectal examination should never be omitted. Prognosis was good if recognized and operated upon early. Chronic appendicitis was met with. The greatest mortality was due to peritonitis and intestinal obstruction. The cases which had been given purgatives furnished the highest percentage of morbidity and mortality.

Dr. SILAS D. MOLYNEUX of Blossburg, Pa., said that he thought our records in abdominal drainage were not better because we did not drain rather than because we drain too much. It was a good plan when you were in doubt to drain. However, the type of infection would help to determine whether one should drain or not. In cases of tuberculosis ordinarily it was a wise thing not to drain. In old gonococcal infection in the pelvis, or other types of infection of long standing it was not necessary to drain for the reason that the pelvic peritonium would take care of infections so well. Ordinarily we drained too much in the upper abdomen. When it was necessary to drain we did not drain thoroughly enough. Several small tubes were better than one large, perhaps one in the pelvis, one in the cecum and one in the right kidney fossa. Two or three small tubes would carry off more pus than one large one. It was better to leave the incision without any suture at all than to close it up so tight. In placing the drain it was important that we did not impinge upon the small bowel. A drain here often caused bad adhesions and intestinal obstruction and consequently we should keep our drain as far away as possible from the small intestine.

Dr. CHARLES A. FIFE of Philadelphia said that he was very glad as a pediatricist to register against the use of castor oil in appendicitis and heartily endorsed the plank of the platform which imposed the duty upon every medical man to report at once to the surgeon and turn over to him every case of suspicious appendicitis in children. As Dr. Alexander had so well said, the cases in children advanced insidiously, but often very rapidly and therefore operation must be done. Very clear evidence of this rapid advance was shown by the experience of the physicians at the Girard College. Here they have a fixed policy of encouraging all the

boys to report at once to the infirmary for the slightest disorder, particularly so-called "stomach-ache" and "bilious attacks." Dr. Wharton had told him that boys who had pain early in the morning were operated upon at 11 o'clock and in that time over 90 per cent. of cases required drainage, showing the rapid advance in children, particularly in the older children.

Dr. WILLIAM L. ESTES of South Bethlehem said that in hearing the paper on Appendicitis in Children the point of frequent mistake in diagnosis ought to be brought out, that was diagnosing for appendicitis a case of pneumonia on the right side. It was a curious thing that those that had come to him with most of these pneumonias were in the beginning central and unless one could bear in mind the cardinal factor Dr. Alexander brought out, the uniform distention and the fact that appendicitis gave so quickly a varying curve of temperature, it was very difficult to make the diagnosis. Time and time again cases of so-called appendicitis had been sent to him for immediate operation which he had found on more careful investigation to be cases of pneumonia.

Dr. F. HURST MAIER of Philadelphia thought one of the best tests of a surgeon's ability was the question of when to drain and when not to drain. The old axiom of "when in doubt drain" should probably be substituted by the more modern axiom "when in doubt don't drain." Of course, he was more interested in pelvic surgery than in general surgery, but there were very few cases of pelvic surgery in which it was necessary to drain. We must always remember in the question of drainage that it carried with it a great deal of morbidity. One of the greatest bugbears in surgery to-day concerning morbidity and also concerning the secondary mortality was postoperative adhesions and they were most frequently the result of drainage.

Dr. J. DE V. SINGLEY of Pittsburgh said that the purpose of a drain was not principally to favor the outpouring or the withdrawal of the products of infection from the abdominal cavity. If the primary focus of infection had been removed or closed the principal thing that a drain did was to stimulate the throwing out of an inflammatory exudate which localized the infection. The omentum was the best abdominal drain. The function of the omentum very readily appreciated was its ability to wall off and isolate areas of infection. The material used for drainage when drainage was absolutely demanded was of the greatest importance and personally he was very strongly opposed to glass or rigid rubber tube, as there could be no question that it was a frequent cause of pressure necrosis with occasional disastrous results. Rubber dam or a soft collapsible rubber tube was infinitely superior. Gauze of any type was one of the worst drains that anyone could use in that it commonly resulted in fecal fistula.

Dr. EMORY G. ALEXANDER of Philadelphia said that he had operated on a boy 11 years of age who had walked into the hospital with a large pelvic abscess. He had been playing around all week. The differential diagnosis was most difficult and important in regard to this subject. He knew of no condition in the realm of surgery which was so hard to diagnose as appendicitis in childhood. Especially was this true in cases with symptoms of pneumonia. He had kept patients under observation after having them in the hospital with all the facilities of making examination and laboratory test and had been unable to make a positive diagnosis for several days. If one wished to drain he had to use a glass tube. He had only one fecal fistula out of 500 cases.

(To be continued.)

X-Ray Finger Prints.—Dr. Henry Beclere of Paris is reported to have proposed to the police service of that city a new and improved method of "fixing" finger-prints for permanent identification. The method calls for the rubbing into the lines and markings of the finger-tips of a preparation of carbonate of bismuth or some other salt, which, when the fingers are photographed by means of the x-ray, shows corresponding opaque marks in the picture thus made. An additional advantage consists in the fact that the radiographic picture shows also the skeleton of the fingers and the outline and special form of the nail.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

One Hundred and Fifteenth Annual Meeting, Held at the New York Academy of Medicine, November 22, 1920.

THE PRESIDENT, DR. CHARLES H. CHETWOOD, IN THE CHAIR.

AFTER the transaction of routine business the following annual reports were presented.

Report of the Board of Censors.—DR. GUSTAV G. FISCH submitted this report, which stated that eight regular, one adjourned, and one special meeting of the Board of Censors was held during the year. Many minor complaints for infractions of the Code of Ethics by physicians and violations of the law by advertising concerns were received and all were disposed of.

Report of the Counsel.—GEORGE W. WHITESIDE, Esq., submitted this report, which showed that the counsel had attended to the usual duties of his office. The report recalled that at the last annual meeting new means of disposing of complaints received by the counsel concerning the unlawful practice of medicine were considered, whereby support and cooperation of the Police Department of the City of New York and of the District Attorney of the County of New York were to be secured and the investigation and prosecution of offenders made through these departments. The Police Department and the District Attorney had expressed themselves as willing to look into and take proper action on all complaints of crimes received and this they had done. Since the society had abandoned the employment of special investigators because of the expense entailed, the counsel had endeavored to carry out the policy of the society for the enforcement of medical laws against unlawful and unlicensed practitioners by stimulating activity in that direction by the Police Department and the District Attorney of the County of New York. Various departments of the city, State and Federal governments, including the State Department of Education, the Department of Health, the District Attorney of the County of New York, and the United States District Attorney had called upon the counsel for advice, and counsel had assisted them in the rigid enforcement of the medical law and the suppression of illegal practices. Pursuant to the resolution adopted at the last annual meeting the counsel conferred with the committee appointed to revise the constitution and bylaws of the society on several occasions and had rendered them opinions on various questions submitted to him relative to the various amendments. The counsel deemed it necessary to make a thorough search into legislative acts relating to the charter of the society and had summarized the various changes made therein since 1813, and all the various legislative acts relative to the practice of medicine in this State since 1813, in order to assist the committee in carrying out its purposes. He had also conferred with the narcotic drug committee and the special committee on public health of the State Society, and had communicated with the Board of Regents concerning the effect of a conviction for violation of the Harrison narcotic law upon the license to practise medicine. The medical statutes of this State forbid one convicted of felony thereafter to practise medicine. The question had been raised, however, whether the conviction of a felony under the Federal law disqualified one from the practise of medicine under our State statutes, and it was to the interest of the profession to have this question promptly decided. To this end proper action would shortly be taken. It must be kept in mind that the legal rights of the medical profession required aggressive exercise for their healthy growth. There was no more important function in the office of the counsel of the society than the vigorous, aggressive, positive assertion of rights under our law in behalf of the profession and the maintenance of respect and obedience to those rights. If a governor was under misapprehension that chiropractors had a right to practise, such mistaken conception must be corrected. When judges of our courts had similar views they must be shown their error. This in the past year had been the privilege and duty of the counsel. The report

then reviewed the activities of the counsel in opposition to the chiropractor's registration bill. The counsel's objections to the bill were based largely upon the method of regulation provided therein. The bill provided that the Chiropractors Society of the State would in substance control the licensing of present practitioners of chiropractic. It was evident from the provisions of this bill that it would be in practical control of the licensing of those who were to be given the privilege to practise. There were further provisions with respect to the institutions whose diplomas should be recognized as a necessary requisite for future applicants for license. This made the Chiropractors Society the judge of the schools. The counsel had shown the Governor clearly that the practice of chiropractic in this State constituted the practice of medicine under the present statute and that those engaged therein who were not licensed practitioners of medicine were violators of the law, and that therefore the proposed bill made as a necessary qualification for the practice of chiropractic that they should have been engaged in violating the present law of the State and that they should be members of the society whose activities constituted a conspiracy against the laws of the State. After reviewing several prosecutions of special interest, he concluded that it might be seen that the medical profession as represented by this society came in contact with the public in many matters of vital importance through the office of the counsel, who became the mouthpiece not only for expressing through the channels of the courts or the Legislature the legal position of the society concerning matters of importance to it and to the public at large, but also to give legal advice of a constructive character for the advancement of the profession, the eradication of injustice to the members, and the creation of increased respect and sympathy for its truths and professional ideals.

Reports of Standing Committees.—Committee on Membership.—DR. FREDERICK H. DILLINGHAM submitted this report, which showed that there had been 231 applicants for membership in the society during the past year, of which 200 were recommended for election and 25 were still in the hands of the committee.

Report of Committee on Public Health.—This committee, of which Dr. Charles E. Nammack was chairman, submitted a report stating that the only matters which had engaged their attention during the year were compulsory health insurance, the proposed establishment of health centers throughout the State, and certain amendments to the Workmen's Compensation law. These matters had been considered by a special committee, of which Dr. Delphy was chairman, and were embodied in his report.

Report of Committee on Legislation.—DR. WILLIAM P. HEALY submitted this report, which showed that six meetings had been held during the spring of 1920, when the Legislature was in session. Forty-one Senate bills were considered and seventeen Assembly bills, and proper advice was given the comitia minora. The chairman had attended hearings at Albany to oppose the Compulsory Health Insurance bill and the Sage-Machold Health Center bill. They had met with the Committee on Narcotic Drug Control and discussed Assembly bill No. 681 with reference to the control of narcotics. At a meeting for the discussion of the Nurses' Attendant bill, Senate bill No. 35, new number 379, the opinion of the Public Health Committee of the Academy of Medicine was adopted.

Report of Special Committees.—Report of the Milk Commission.—DR. ROWLAND G. FREEMAN submitted this report, which stated that the amount of certified milk had increased during the past year by some 1500 quarts a day. The same inspector who had been doing the work in the past made 225 visits to dairies during the year. She had devoted 58 days to laboratory work and had supervised 30 tuberculin tests. She had traveled 28,000 miles by railroad, over 1000 miles by motor and 700 by ferry and long distance trolley. The amount collected by the Milk Commission was \$6,147.90, of which \$5,758 was paid out, leaving \$389.09 to the benefit of the society. The commission was now certifying some 13,740 quarts of milk daily. They were still making inspections and reporting to the Milk Commission of the Medical Society of Westchester and that of the Bronx.

Report of Special Committee on New Members.—Dr. EBEN FOSKETT submitted this report, which stated that the society had in its membership nearly 3000 of the 6000 medical practitioners of this city. During the year 300 men had filed licenses to practise medicine in the office of the County Clerk. Each of these was invited to join the society. Approximately 800 invitations to join the society, accompanied by application blanks, were sent out during the year.

Report of Public Health Education Committee.—Dr. ESTHER L. JEFFERIS submitted this report, in which she stated that eleven years ago the Public Health Education Committee was a pioneer in the medical lecture field through which the public was given free lectures on the prevention of disease and instructed in measures for the attainment of health. The success of these lectures was so pronounced that soon the City Department of Health, the Board of Education, the Y. M. C. A., and other organizations, followed in the footsteps of the Public Health Education Committee and presented similar free lectures under their own organizations. The lectures of the Public Health Education Committee were always held in Hosack Hall, New York Academy of Medicine, and while popular and well attended, had not reached many of the people for whom they were intended, because the academy was a distance from many who might have attended. Other organizations had been able to overcome this disadvantage by the use of school buildings in each school district, and special organization buildings, so that their free medical lectures became practically a neighborhood affair, and a neighborhood interest aroused pride and enthusiasm. This lecture work had always been financed within the appropriation of \$300 granted by the comitia minora. The financial requirements to give the work in 1920 would have been at least two or three times greater than the original appropriation, so after due consideration there seemed no vital reason why the medical society should be taxed for more financial aid when there were already so many free health lecture courses in existence. If the work was presented it must be done on a bigger scale than ever before, and the winter of 1920, with its unrest and chaotic state, did not seem to be the propitious time for launching new lecture courses and demanding of medical men and women time and energy free, when both were needed to meet their own post-war problems. During the past eleven years the lectures had been the means of placing the physician before the public not as the medical man or woman, who came only in sickness to relieve or cure, but as the physician who insisted that patients gain knowledge of right health and life measures. This side of the work of the committee had been paradoxical, since it had apparently tended to decrease medical practice; practically it had done just the opposite and had established a relationship between the medical profession and the public so big, broad, and sane, and on so new a basis that there had been born a third relationship between the public and the physician, that of preventive medicine. If the winter of 1920-1921 presented conditions favorable for the presentation of the lecture work on the right scale, the same earnest endeavor and effort they had shown heretofore would be made by the members of the committee to assure the continued success so splendidly gained in the past.

Report of Committee on Narcotic Drug Legislation.—Dr. ALFRED A. PRENTICE submitted this report, in which he stated that he was also chairman of the special committee of the American Medical Association on the narcotic drug situation in the United States, which had held many conferences during the year in New York, Chicago, Washington, Philadelphia, Atlanta, and New Orleans. The details of these conferences were embodied in the published report of the proceedings of the house of delegates of the American Medical Association in annual session at New Orleans, April 20 to 30, 1920. The recommendations, in conclusion, were unanimously adopted by the American Medical Association, of which section 1 read as follows: "That the ambulatory treatment of drug addiction, as far as it related to prescribing and dispensing of narcotic drugs to addicts for self administration at their convenience, be emphatically condemned." The Medical Society of the State of New York adopted a similar resolution

at its annual meeting last March. The Cotillo bill was endorsed by the Medical Society of the State of New York on recommendation of its committee on legislation and on medical economics at this meeting, and at the April meeting of the Medical Society of the County of New York the bill was endorsed and the chairman of the committee on narcotic drug addiction was instructed to support the bill at a hearing held before the Senate Public Health Committee at Albany on April 15, 1920. The report quoted the amendment to the Public Health law providing for a division of narcotic addiction in the State Department of Health and also statements from the Bureau of Drug Control of the State Department of Health of Pennsylvania, and by the United States Commission of Internal Revenue, showing that the attitude of condemnation of the so-called reductive ambulatory treatment of drug addiction was now becoming generally recognized and adopted.

On motion these reports were accepted and placed on file.

Report of Special Committee on Compulsory Health and Workmen's Compensation Insurance.—Dr. EDEN V. DELPHEY submitted this report, which showed that during the year this committee had made a careful study of the subject of and the bill presented to the Legislature on compulsory health insurance, the Workmen's compensation insurance in its application to the medical profession, especially that portion relating to occupational diseases, and the freedom of choice of physician by the injured person coming under the provisions of the law, and of the subject of "Health Centers." On February 26 the chairman sent a letter to the secretaries of all the State medical societies in the United States endeavoring to ascertain the sentiment of the members of these various societies on the subject of compulsory health insurance; whether they had instructed their delegates to the A. M. A. on the subject; inquiring their opinion as to the best method of bringing the matter before the A. M. A. for action thereon, and requesting a list of their delegates to the house of delegates of the A. M. A. He sent a letter to the delegates to the Medical Society of the State of New York, calling their attention to the imperative need of taking action on the subject, and enclosing the substance of a resolution which he expected to introduce in the house of delegates of our State Society indicating that it was desirable to instruct our delegates to the A. M. A. to introduce a resolution in the house of delegates of the A. M. A. and to support the resolution in every way possible. He also sent a letter to all the delegates to the house of delegates of the A. M. A., inviting their attention to the propaganda for a scheme which could but have a serious and destructive effect upon the most altruistic profession on the face of the earth—the medical profession—that it would tend to destroy individuality and prevent the proper class of men from entering the profession in the future, whereby the entire people would suffer. He was pleased to report that resolutions against the iniquitous scheme for compulsory health insurance were unanimously adopted both by our State Society and by the house of delegates of the A. M. A. After a careful study of the subject and conferences with the New York State Industrial Commission, the committee formulated amendments to the Workmen's Compensation law, as follows:

Section 13. *Treatment and care of injured employees.* "The employer shall (promptly) provide for an injured employee such medical, surgical, or other attendance and treatment, nurse and hospital service, medicines, crutches and apparatus as the nature of the injury may require during sixty days after the injury; but the commission may, where the nature of the injury or the process of recovery requires a longer period of treatment, require the employer to provide the same. (If the employer fail to provide the same, the injured employee may do so at the expense of the employer. The employee shall not be entitled to recover any amount expended by him for such treatment or services unless he shall have requested the employer to furnish the same and the employer shall have refused or neglected to do so.) *An injured employee shall have the right to choose any physician duly licensed to practise medicine in this State to attend and treat him*

for the injury as hereinbefore provided, subject to the supervision of the commission. All fees and other charges for such treatment (and) services, medicines, crutches, and apparatus, shall be subject to regulation by the commission as provided in section 24 of this chapter, and shall be limited to such charges as prevail in the same community for similar treatment of injured persons of a like standard of living."

SUGGESTED AMENDMENTS WORKMEN'S COMPENSATION LAW.

"Amend section 26 by adding after the word 'therefrom,' section 26, page 57, twentieth line, edition July, 1919, the following: 'Claims for medical services and for services or treatment rendered or supplies furnished pursuant to section 13 of this chapter and approved by the commission in conformity with section 24 hereof, shall constitute the person or persons owning such claim or claims a party in interest hereunder for the purpose of permitting the filing with the County Clerk of the decision of the State Industrial Commission as herein provided, and such person shall to the extent of the amount of his claim so approved by the commission be deemed to have all the rights of a judgment creditor in such claim and may enforce his rights thereto with the same effect as though the judgment stood of record in his name and for his benefit.'"

"Amend section 3 by changing sub-section 7, page 22, edition of July, 1919, to read as follows: "'Injury' and 'personal injury' mean only accidental injuries arising out of and in course of employment (and) such disease or infection as may naturally and unavoidably arise therefrom (.), and such 'occupational' diseases as are scheduled under article 2a.'"

The committee was of the opinion that the occupational diseases amendment to the Workmen's Compensation law was a corollary to the law itself, and that if the medical profession were properly protected in its rights and privileges as provided for in their suggested amendments the enactment of some such an addition to the Workmen's Compensation law should be approved. The Sage-Machold Health Centers bill was thoroughly studied by this committee, and in order that they might come to a just and proper conclusion as to its merits, they sent out circular letters to all the delegates to the State Society, outside of New York City, and to all the secretaries of the county societies, proposing a series of questions and requesting replies thereto.

Dr. Delpey exhibited this questionnaire and the tabulated reply thereto, on the basis of which the committee recommended that the society take measures to have the suggested amendments to the Workmen's Compensation law introduced into the next session of the Legislature. The committee also recommended that the society take measures to oppose any and all further health insurance bills, and that the society oppose the scheme for "health centers," as their survey indicated that it was not needed—that the people in the rural districts were, as a whole, as well cared for medically as were the people as a whole in the cities; that the general medical care was adequate now; that both the poor and the well-to-do preferred to have their own physician attend and care for them in their illnesses, whether they could afford to pay for it or not; that the medical profession would in the future, as it had always done in the past, look after the poor and needy in the times of medical need and distress, and that there was no real need for a scheme which would have for its effect the production of a large number of offices to be scrambled for by both political parties, with its attendant graft and neglect of those for whom the plan was supposed to provide an improved medical care. The committee respectfully requested that those portions of the report which referred to the amendments to the Workmen's Compensation law, and to the "health centers" be postponed until the December meeting of this society, and that they be published in the December number of the New York State Journal of Medicine in order that members might have the subject before

*Matter in brackets () to be omitted; matter underscored is new matter.

them for study and consideration before being called on to decide what their action should be.

It was moved, seconded and carried that no action be taken on this report until the next meeting.

Annual Report of the Comitia Minora.—Dr. DANIEL S. DOUGHERTY submitted this report, which consisted of an outline of the work of the society as transacted at the stated meetings during the past year.

Revision of the Constitution and By-laws.—Dr. DANIEL S. DOUGHERTY then read seriatim the proposed amendments to the constitution and by-laws of the society, which were discussed and voted upon. The chief changes proposed were in a general way the following: (I) The Comitia Minora was made more democratic by the addition of four new members elected by the society. These members were: (a) Chairman of the Committee on Civic Policy; (b) chairman of the Committee on Membership; (c) chairman of the Committee on Legislation; (d) assistant treasurer. (II) Creation of a Committee on Civic Policy, whose function should be to gain information concerning those questions which determine the relation of the medical profession to the commonwealth and to advise the society concerning such questions. (III) The routine procedure for stated meetings required that motions which affected the general policy of the society should be presented in writing and should be referred to the Comitia Minora for consideration and advice. The report of such motions to be made sometimes on the same evening but usually at the following meeting. (IV) Citizenship or declared intention of citizenship was made necessary for membership in the society. (V) The dictation was adjusted to conform to legal and literary requirements.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

OREGON STATE BOARD OF MEDICAL EXAMINERS.

July 6, 7, 8, 1920.

(Continued from page 1050.)

DIAGNOSIS.

1. Give the diagnosis of pituitary disease.
2. Differentiate encephalitis lethargica and tuberculous meningitis.
3. What is the significance of nystagmus in nervous disease?
 4. Give the differential diagnosis of enlargement of the cervical glands.
 5. Give diagnosis of carcinoma of the lung.
 6. In a case of suspected gonorrheal arthritis with no perceptible discharge, how would you proceed to demonstrate the presence and location of the infection?
 7. Differentiate delayed resolution following croupous pneumonia from fluid in the pleural cavity.
 8. Discuss the reaction of degeneration as to diagnosis and prognosis in peripheral facial paralysis.

PATHOLOGY.

1. Describe branchial cyst, carbuncle, deciduoma.
2. Give the pathology of phlegmasia alba dolens, or milk leg.
3. (a) What lesion presents the largest heart? (b) Aneurysm of which portion of the aorta gives most symptoms? (c) Which is the smallest pathological kidney? (d) Which is the largest spleen?
4. (a) Describe the eclamptic liver. (b) What is rana?
5. Define paronychia, astereognosis, ischemia, vitiligo, vitamine, Koplik's spots, hemolysis.
6. Detail the coincident pathology associated with chronic obstructive hypertrophy of the prostate.
7. (a) Describe fatty degeneration, give the etiology and tissues affected. (b) Tell what you know about amyloid degeneration.
8. Give the pathology of angina pectoris.

PRACTICE OF MEDICINE.

1. Give the symptomatology and course of pernicious anemia, aside from the blood findings.
2. Discuss chorea and give diagnosis and treatment.
3. Give a method of selecting a donor for blood transfusion.

4. Give the diagnosis and medical treatment of pyloric ulcer.
5. How would you cure a case of bronchial asthma? Also give the treatment of an attack.
6. State the duration of the average febrile stage of measles, scarlet fever, typhoid fever, variola and lobar pneumonia.
7. (a) Give the differential diagnosis and treatment of dermatitis seborrhoica. (b) Give treatment of acne rosacea.
8. Give the symptoms and signs of brain syphilis.

OBSTETRICS.

1. Give measurements of the normal pelvic inlet.
2. From what is the placenta formed and what is its function?
3. Define position, presentation, and rotation of the fetus.
4. Give the symptoms and treatment of eclampsia.
5. Causes, symptoms, and treatment of ectopic gestation.
6. How would you treat persistent vomiting of pregnancy?
7. How would you manage a face presentation after the chin has rotated to the hollow of sacrum?
8. Give indications for, and technique of an abdominal cesarean section.

ANSWERS.

DIAGNOSIS.

1. *Pituitary disease* may be of two kinds: (1) in which the internal secretion is in excess (*hyperpituitarism*); and (2) in which the internal secretion is diminished or absent (*hypopituitarism*). In *hyperpituitarism* there are signs of gigantism, or of acromegaly; the gland is enlarged; there may be glycosuria; the temperature is subnormal; other parts beside the bones may be enlarged; excessive fatness, infantile stature and development of the genitals may be noticed. In *hypopituitarism* there will be noticed excessive fatness, atrophy of the genitals and infantilism.

2. Fever, torpor, and ocular paralysis may occur in both conditions. The cardiac and respiratory difficulties are greater in tubercular meningitis. By lumbar puncture the diagnosis may be made, in encephalitis the cellular elements are less marked, and in tubercular meningitis careful technique will reveal the presence of the tubercle bacilli.

3. *Nystagmus* "occurs as the result of hereditary visual weaknesses, of refractive errors of various kinds, in albinos, and in chronic hydrocephalus. It is found usually in neurotic persons who have ocular defects, in multiple sclerosis, and sometimes in chorea. It occurs also in hereditary ataxia, tumors, especially of the cerebellum, and mid-brain, and in meningitis. It occurs in miners and is called miner's nystagmus."—(Dana's *Text-Book of Nervous Diseases*.)

4. *Enlargement of the cervical lymph glands.*

"Cervical lymphadenitis may be confused with lymphadenoma. The former, as a rule, first appears in the submaxillary triangle; the latter, in the occipital or sternomastoid glands. The former are more tender, softer, and less movable than the latter. Tuberculous glands weld together, they are apt to remain localized for a considerable time, and they tend to soften. They may be accompanied by other tuberculous manifestations. Lymphadenoma from the start affects many glands; it may arise simultaneously in several regions, although in some cases there is a distinct beginning in one region. Lymphadenoma shows very little tendency to suppurate, and does not break down except late in the course of the disease, and is accompanied by great debility and anemia. Tuberculin tests may aid in the diagnosis, but a difficulty is that Hodgkin's disease and tuberculosis may coexist. Malignant gland-tumors infiltrate adjacent glands and other structures, binding skin, muscles, and glands into one hard, firm mass."—(Da Costa's *Modern Surgery*.)

5. *Carcinoma of the lung*: "Pulmonary carcinoma is most common in middle age. The disease is often strikingly symptomless for long periods, or baffling and indeterminate, the size and location of the growth being the chief factor; obstinate and violent cough may

or may not be present. Sputum may be entirely absent, or like prune juice or currant jelly, blood streaked or even purulent and of gangrenous odor, and contains compound granule cells. Involvement of the pleura may produce severe pain and the dyspnea usually present in some degree may be strikingly paroxysmal; pressure symptoms may be marked and are often identical with those of aneurism. Fever is often noted as the disease advances, profuse hemorrhage occasionally occurs, and there may be marked displacement of the heart. Secondary growths are usually suggested by a primary lesion, but primary ones are frequently beyond a positive diagnosis. The x-ray may prove valuable in such cases, and if the growth be accessible and of considerable size it may yield percussion dullness, usually without tubular breathing, and increased fremitus, more rarely, if attached to a large bronchus, both phenomena.

6. In the case of suspected gonorrheal arthritis, some of the fluid from the joint may be obtained by aspiration, and a bacteriological examination made.

7. An exploratory puncture will promptly show the presence of fluid in the pleural cavity.

8. *Reaction of degeneration in peripheral facial paralysis*: "The electrical reactions are characteristic and important, since typical or partial degeneration reactions can usually be observed. For a few days there is an increase in irritability of the muscles to both faradic and galvanic currents. This is followed by a gradual loss or diminution in faradic irritability, while the galvanic irritability remains sometimes increased for a while and then falls. At the same time a reversal of poles and a sluggish contraction, particularly the latter, may be noted. At the end of five or six weeks faradic irritability ought to begin to return. Great variations are found in the electrical reactions, dependent upon the severity of the case. For example, in very severe cases the electrical irritability may be almost or entirely absent for days and even weeks. If the disease lasts for two months or more and the palsy is not a complete one, secondary contractions begin to appear. The mouth now becomes drawn to the affected side, and the nasolabial fold becomes deeper than that on the sound side. In smiling or speaking or other facial movements there is an excess of movement on the paralyzed side, the teeth and upper gums in particular showing abnormally. This is particularly the case in old palsies beginning in childhood."—(Dana's *Text-Book of Nervous Diseases*.)

PATHOLOGY.

1. *Branchial cyst* is a cyst developed in an incompletely closed embryonic gill cleft.

Carbuncle is a lesion in which several contiguous hair follicles are infected; there are several centers of necrosis; the process is similar to that of furunculosis, but is more extensive and more severe.

Deciduoma is a tumor derived from the chorionic villi.

2. *Phlegmasia alba dolens*. "Two separate pathological conditions, which are sometimes combined, are included under this term. (1) *The thrombotic form of phlegmasia* is a septic thrombophlebitis of the femoral or other veins of the lower limb. This is usually continuous with a similar process in the uterine veins, but it may be independent. The phlebitis and thrombosis tend to spread down the limb, and the venous return is obstructed, with the result that the whole lower limb from the foot up becomes markedly edematous. The veins of the upper limbs are occasionally, but rarely, affected in the same way. The swollen limb pits on pressure, and in thin patients the affected veins may be felt as tender cords. (2) *The lymphatic or cellulitic form* is really a deep cellulitis, usually but not invariably continuous with a parametritis. The glands in the groin are frequently enlarged and tender. The swelling becomes very tense and hard, and soon ceases to pit on pressure, while the skin becomes white and glossy. If the skin is pricked the fluid that exudes is coagulable lymph, not the simple serum of the thrombotic edema. The lymphatic form—the true 'white leg'—is certainly septic in origin. It is rare now since the introduction of antiseptic methods. The thrombotic form is probably also septic in origin in most cases, the phlebitis being secondary to the infec-

tion of the thrombus. But the condition of the blood is an important element, for the disease is much commoner after serious hemorrhages during labor, and in anemic women."—(Johnstone's *Text-Book of Midwifery*.)

3. *The largest heart* is found in aortic regurgitation. Aneurysms of the arch of the aorta gives the most symptoms.

The smallest pathological kidney is found in chronic interstitial nephritis.

The largest spleen is found in spleno-medullary leukemia.

4. *The eclamptic liver*: "The lesions in the liver vary from congestion with granular and fatty degeneration to necrosis with almost complete dissolution of the liver parenchyma. This necrosis begins at the center of the lobule and extends toward the periphery, leaving only a mass of granular detritus surrounding the central vein, the nuclei and cell contents disappearing with only a reticular network in the place of the liver cells. Thromboses with hemorrhage occur throughout the whole lobule more often at the periphery. The organ may be swollen or diminished in size, according to the change in the parenchyma. It usually presents a yellowish color and may have hemorrhages under the capsule."—(Cragin's *Practice of Obstetrics*.)

Ranula is a retention cyst occurring in the duct of the sublingual salivary gland, rarely in one of the other glands; it is a mucocele in the floor of the mouth.

5. *Paronychia* is a cellulitis of the parts around a nail.

Astereognosis is the inability to recognize the form of objects held in the hand.

Ischemia is a localized anemia.

Vitiligo is a condition in which areas of the skin have lost their pigment.

Vitamines are unidentified substances which are necessary for the nutrition of the body, and which are ordinarily ingested in small amounts with the food.

Koplik's spots are irregular spots of a red color, with a bluish-white center, found on the mucous membrane of the lips and cheeks at the beginning of an attack of measles.

Hemolysis is destruction of the red blood corpuscles with setting free of the hemoglobin.

6. *Hypertrophy of the prostate* is very common in patients over fifty-five. The different varieties are: (1) General enlargement of all the tissues; (2) local enlargement, giving rise to definite tumors in the gland, which may be glandular (adenoma) or fibromatous. These tumors may project toward the rectum, into the urethra, or up into the bladder. The prostate urethra is always lengthened and distorted, so that micturition is interfered with. If the median lobe is enlarged the internal urinary meatus is more or less blocked. *Symptoms* begin with frequency of micturition, then some difficulty in the act of micturition, with diminution in the power of projection. Some pain and tenesmus occur later. Secondary changes in the bladder depend on the amount of obstruction. Hypertrophy and sacculation of the ureters and hydronephrosis are produced still later. As atrophy of the bladder comes on a certain amount of residual urine remains after each act of micturition. As this increases distention and atony are found with overflow incontinence. Cystitis soon comes on, and may be followed by septic changes in the kidney. The early changes may be unnoticed till overflow incontinence appears. Priapism may occur in the early stages.—(*Aids to Surgery*.)

7. *Fatty degeneration*: "In fatty degeneration there is an accumulation of larger and smaller droplets of fat in the cell, sometimes so slight as to be scarcely visible, sometimes so great as largely to replace the protoplasm, crowding the nucleus to one side. Cells in excessive fatty degeneration may disintegrate, forming an oily detritus in which, especially when much moisture is present, cholesterol crystals may form by decomposition of the fat. To the naked eye, organs in a condition of marked fatty degeneration are usually larger and softer than normal, have a grayish-yellow color, or are mottled with yellowish streaks or patches, and the normal markings of cut surfaces are more or less obscured. Fatty degeneration may be associated with or may follow albuminous degeneration, and may occur under similar general conditions, as in infec-

tions, poisoning, etc. It is often associated with the processes of necrosis and disintegration in dead cells and dead tissue. It may be due to local or general disturbances of nutrition, from a great variety of causes—disturbances which either directly affect the life processes of the cells themselves or which produce alterations in their nutritive supply. In addition to its local occurrence, as a result of local disturbances of circulation in the vicinity of inflammations or in tumors, it is apt to occur in the liver, heart muscle, and kidney, in chronic exhausting diseases, and in conditions and diseases in which profound anemia is incident, in senility, or as the result of the action of certain poisons, such as phosphorus and arsenic."—(Delafield and Prudden's *Text-Book of Pathology*.)

Amyloid degeneration: "This is a process by which the basement substance of various forms of connective tissue, and especially the walls of blood vessels, become swollen and thickened by their conversion into a translucent, firm, glassy, colorless material, albuminous in character. . . . Parts in which the lesion is marked are usually enlarged, and some organs, the liver, for example, may reach a very large size. . . . It is not yet known whether amyloid degeneration is due to a direct transformation of the tissue, or is an infiltration by some abnormal material formed elsewhere and brought to it, or is derived from the blood. It occurs most frequently and abundantly in the liver, spleen, kidneys, intestinal canal, and lymph nodes; but it may occur in other parts of the body. . . . It most frequently occurs in connection with severe wasting diseases, particularly in those involving chronic suppuration and ulceration, especially of the bones. It is common in tuberculosis, syphilis, and the cachectic condition induced by malignant tumors, and is occasionally seen in severe malarial infection, dysentery and leukemia."—(Delafield and Prudden's *Text-Book of Pathology*.)

8. *Angina pectoris*: "Various theories have been advanced to explain the occurrence of angina. That of *intermittent claudication* is based upon the analogous attacks of pain which sometimes occur in the legs when their arteries are partially obstructed. In such a case the circulation suffices for rest or restful movement, but prolonged exertion causes cramplike pain and temporary lameness (claudication). Similarly in a heart poorly supplied with blood (ischemic), or in which the driving power is defective, exertion may cause a temporary exhaustion of the muscle. This condition would be favored by increased peripheral tension, which is sometimes permanently present, and sometimes exists during an attack. It may also be produced by chill (contraction of the peripheral arterioles). But in some cases the tension is permanently low, and then we may suppose that a slight increase of work, which would be no obstacle to a healthy heart, is sufficient to cause exhaustion to a damaged one. It is in cases of hindrance to the work of the *left ventricle* that angina occurs.

Other theories are that the pain is a neuralgia of the cardiac nerves, or that it is due to tension of the ventricular walls, induced by acute dilatation. Allbutt considers that it is not truly cardiac, but originates in the first part of the aorta. Mackenzie, adopting generally the claudication theory, compares the pain to that produced by the obstructed evacuation of other hollow viscera (e.g. biliary colic), and regards it as a protective reflex."—(Wheeler and Jack's *Handbook of Medicine*.)

PRACTICE OF MEDICINE.

1. *Pernicious anemia* begins insidiously, with languor, muscular weakness, and pallor; palpitation of the heart, dyspnea, attacks of syncope, and edema may follow. The pulse is large and soft, hemic murmurs are often present; later on a remittent fever may develop, together with nausea, vomiting, diarrhea, anorexia, and disorders of vision. The weakness progresses.

2. *CHOREA*.—*Symptoms*: (1) Irregular and purposeless convulsive movements of the limbs, trunk, face, and tongue, rendered worse on attempting to execute voluntary acts and in fine movements such as picking up pins, conveying a cup to the lips, writing, or touching a particular point. The movements of the trunk, as the child lies in bed, may cause the body to be first twisted to one side, and then suddenly to the other. The

movements cease as a rule during sleep, but may be so violent as to prevent it. The condition may affect one side only (hemichorea). (2) Incoordination, manifested in the movements of writing, in unsteady gait, and in irregular movements of respiration, the diaphragm and intercostal muscles failing to act together. Muscular weakness is a later symptom as a rule. (3) Irregular and rapid action of the heart, sometimes amounting to "delirium cordis." (4) Soft systolic murmurs at the apex of the heart, due to endocarditis, or hemic murmurs at the base. There may be other rheumatic phenomena. (5) Altered mental conditions are sometimes marked, the patient laughing or crying in turns on being spoken to. Increased irritability is common and in some cases, chiefly in adults, there may be maniacal excitement.

Treatment.—(1) *Rest in bed* is the first and essential point of treatment. (2) Arsenic in increasing doses, cod-liver oil, abundant food, and careful attention to the bowels. Antipyrin or phenacetin in increasing doses is also useful. Salicylates are of value only in rheumatic complications. When the movements are very severe, chloral may be freely given. (3) As soon as convalescence seems established, allow the patient plenty of fresh air and gymnastic exercises."—(Wheeler and Jack's *Handbook of Medicine*.)

3. *In blood transfusion:* "The donor should be a healthy adult, with a negative Wassermann reaction. His serum should not agglutinate the corpuscles of the patient, and the patient's serum should not agglutinate the donor's corpuscles. Agglutinins should be excluded by tests done immediately before the transfusion and a single examination is not sufficient to establish the compatibility of two bloods on all future occasions. If agglutinins are absent hemolysis will also be absent. If there is great urgency, and testing of the blood of patient and donor are impracticable, a small preliminary transfusion should be done half an hour before the main mass of blood is transfused, so that gross incompatibility may be recognized in time. Febrile reactions occur after about 25 per cent. of transfusions, even though the bloods of donor and patient have been shown to be compatible. Rigors occur in about 10 per cent. of the cases."—(From DaCosta's *Modern Surgery*.)

4. In *gastric ulcer* "the degree of digestive disturbance varies. The tongue is clean, there are generally nausea and vomiting. There is tenderness over the epigastrium, with pain in the same region from a half to two hours after food, also often referred to the back, and relieved by vomiting. Hematemesis may cause anemia with a hemic murmur and weakness. In the acute ulcer hemorrhage is copious, in the chronic ulcer small occasional hemorrhages are the rule. In a certain number of cases melena is present. Constipation is frequent; there is no fever.

"*Ulcer of the duodenum:* The signs and symptoms much resemble those of gastric ulcer, with the particular features that the pain is nearer the right costal margin and its time incidence is later—two, three, or four hours after food. The pain is relieved by taking food, which causes closure of the pylorus and so prevents the onward passage of acid chyme over the ulcerated surface. Vomiting is not so common and does not relieve the pain. Hematemesis is rare, but melena is common."

In *gastric carcinoma* "a tumor may be felt, most often in the region of the pylorus, next in the epigastrium over the transverse colon, or there may be merely rigidity of one rectus muscle (more often the right). Secondary nodules may be found near the navel, in the liver, lungs, and lymphatic glands; a group of the latter just above the left clavicle is frequently palpable. According to the situation other conditions may arise—a dilated stomach if the growth is at the pylorus, a contracted stomach if at the cardiac end, adhesions, fistula or peritonitis, ascites—from implication of the peritoneum—edema of the legs from secondary deposits in the retroperitoneal glands pressing upon the inferior vena cava. Pain between the shoulder blades, or in the lumbar region. It is more constant than in chronic gastritis or ulcer, and has no relation to food or the period of ingestion. Vomiting may be absent; if present it will not relieve the pain, and may also have no relation to food. Anorexia is almost always present.

Hematemesis occurs in about 50 per cent. of cases only, the blood is only rarely like that in gastric ulcer, but is usually much altered—the so-called *coffee-ground vomit*. Cachexia (a condition of the body resulting from wasting with anemia) is much more marked than in any other pathological condition of the stomach. A leucocyte count is of value, for post-prandial leucocytosis is absent. Constipation is often present."—(Woodward's *Manual of Medicine*.)

Medical treatment of gastric ulcer: Rest and a light and easily digested diet are absolutely essential. Abstinence from food by stomach and gastric lavage with feeding may be necessary for a time. Sodium bicarbonate, bismuth subnitrate, silver nitrate, and opium are the most frequently used drugs. Pain, vomiting and hemorrhage are treated as they arise; perforation demands prompt operative interference.

5. *Treatment of asthma:* "Careful attention must be given to all the circumstances of the patient's life. Some do much better in the city than in the purer atmosphere of the country; but climatic treatment must be instituted with reference to the response of each individual patient. The diet must be carefully regulated: the gouty and the obese must be abstemious; and in all cases, particularly in those disposed to flatulency, it is wise to advise the heavy meal in the middle of the day, and the partaking of very little food toward evening. The bowels should be opened at least once daily. Sleeping in a room the atmosphere of which is laden with steam (impregnated or not with the vapor of oil of eucalyptus, oil of pine, etc.) or with the fumes of burning nitre may secure freedom from nocturnal attacks and a consequent peaceful sleep. All sources of local irritation (nasal, pharyngeal, etc.) must be remedied.

"*During the attack* relief may be obtained by the inhalation of amyl nitrite, or chloroform, or the fumes evolved by burning the leaves (cigarettes) of belladonna, stramonium, lobelia, hyoscyamus, tobacco, or by burning paper impregnated with potassium nitrate; by drinking hot coffee and whiskey or spirit of chloroform; or by the hypodermic use of morphine (combined with atropine or cocaine), or pilocarpine—to be employed with caution. Tincture of lobelia in dose sufficient to produce the physiological effect is often efficacious, but it should not be employed when the heart is weak. An emetic sometimes assists in expelling retained secretions. An imminent attack may sometimes be ward off, or aborted, by the prompt use of amyl nitrite, nitroglycerin (1/50 grain hypodermically), or chloroform.

"*Between the attacks* no drug is so useful as potassium (or sodium) iodide, combined with lobelia. From time to time one of the bromides also may be added. Nitroglycerin is quite useful in some cases, especially in those with high arterial tension. Adrenalin chloride (hypodermically), euphorbia pillulifera, arsenic, the compressed air of the pneumatic cabinet, oxygen, etc., appear to have been useful in some cases. When the heart is weak strophanthus, or digitalis, in small doses, is serviceable."—(Kelly's *Practice of Medicine*.)

6. *The average duration of the febrile stage:* In *measles*, is about four to six days; in *scarlet fever*, is about six or seven days; in *typhoid fever*, is about thirty days; in *variola*, is about two or three weeks, but is very variable; in *lobar pneumonia*, is about six to ten days.

7. *Dermatitis seborrhoica.* Differential diagnosis: "It may be distinguished from ordinary eczema by its origin in the scalp, the tendency to downward extension, the absence of well-developed vesicles, and pustules, the mild character of the inflammation, the greasy character of the scales, the superficiality of the patches, the absence of marked infiltration, the tendency to crescentic or annular configuration; and the mild grade of the itching. The affection may bear a close resemblance to pityriasis rosea, but the latter seldom, if ever, attacks the scalp; it, moreover, is often preceded by a primitive patch on the trunk or extremities. The lesions are often oval, the long diameter running parallel to the long axis of the ribs; the centers of the lesions are fawn colored and covered with fine scales which are not greasy. The itching is variable, often severe. Pityriasis rosea runs a rapid course, with spontaneous cure, in from six to eight weeks; this is not true of

dermatitis seborrhoica. In psoriasis, the distribution of the eruption is dissimilar; patches about the elbow and knees bespeak a psoriasis; the scales in psoriasis are silvery.

Treatment: The best remedies are sulphur, resorcin, salicylic acid, and ammoniated mercury.—(From Schamberg's *Diseases of the Skin*.)

Treatment of acne rosacea: Internal and external remedies are both of importance. The cause or causes of the disease must be investigated. When the stomach is at fault the diet should be carefully regulated. Condiments, alcohol, tea, starchy and sugary foods and all sorts of stimulating articles are to be prohibited. Due attention must be paid to the condition of the bowels. In the various forms of dyspepsia, nux vomica, the stomachic bitters, mineral acids, alkalies, etc., are to be prescribed. A few cases will require the use of iron, strychnine, codliver oil, and like tonics. **Local treatment:** The sulphur preparations are valuable. Excellent results often follow the use of the "compound zinc sulphide lotion," or Kummerfeld's solution. When the capillaries are enlarged they may be destroyed by scarification, by slitting them up with a fine knife, or by insertion of the electrolytic needle. In hypertrophic cases ablation of the diseased tissues may be performed with a knife or scissors. X-ray treatment is of value.—(From Schamberg's *Diseases of the Skin*.)

8. **Symptoms and Signs of Brain Syphilis:** "In its most common form this shows itself by a gradual development of severe and persistent headache. This is usually associated with vertigo, sometimes with nausea and vomiting. After the headache has developed and has lasted for a time, or even without much delay, there comes on sometimes an attack of hemiplegia. Preceding the hemiplegia, or in some cases without the hemiplegia, there are paralyzes of the cranial nerves, more especially of the nerves of the eye. Optic neuritis is somewhat frequent. The pupils may be irregular in outline and sluggish to light. There may be, before any paralyzes develop, attacks of epileptic convulsions, either general or partial. Without any paralyzes or with simply cranial-nerve paralyzes, there may develop attacks of somnolence and coma. Even if such attacks do not appear, the patient often shows a mental irritability and weakness, a slowness of the reasoning process, and incapacity to fix the attention such as is observed in connection with brain tumors, only with nerve syphilis these symptoms are not usually so marked. Polyuria and polydipsia are symptoms which are occasionally met with. The disease may take the form of a meningo-encephalitis producing symptoms of mental and physical disturbance not distinguishable from early paresis (meningo-vascular paresis)."—(Dana's *Text-Book of Nervous Diseases*.)

OBSTETRICS.

1. The normal pelvic inlet measures: About four inches in the antero-posterior diameter, about four and a half inches in the oblique diameter, and about five inches in the transverse diameter.

2. **Formation of the placenta:** "The placenta is formed by the fusion and intergrowth of the decidua basalis, which forms the maternal portion of the placenta, and the chorion frondosum, which forms the fetal part of the placenta. As a separate organ, the placenta dates from the third month of pregnancy, and from that time gradually increases in size until the termination of pregnancy. The chorionic villi lose Langhans' layer of cells, and embed themselves into the interglutular stroma of the decidua basalis, and sometimes penetrate the mouths of the small veins. The syncytium also penetrates the endothelium of the decidua arterioles, and large blood sinuses are thus formed. By this arrangement, the fetal and maternal blood, while kept separate, are brought into such close contact that osmosis may readily occur between them, thus permitting the absorption of nutritive material from the maternal into the fetal circulation, the excretion of urea and other waste products of fetal metabolism, the passage of oxygen to the fetus, and the excretion of carbon dioxide from it.

"The functions of the placenta may be summed up as follows: (1) It is nutritive, allowing of the passage of nutritive material to the fetus. (2) It is respiratory. Oxygen passes to, and carbon dioxide from, the fetus.

(3) It is excretory, allowing the escape of urea and other products of fetal metabolism. (4) It has a glyco-genic function. Glycogen is stored in its cells for the future use of the fetus. (5) It is iron storing, by which iron in organic combination is passed from the maternal circulation into the fetal circulation to be stored in the liver cells of the fetus, in order to aid in the formation of new colored blood corpuscles."—(Lyle's *Manual of Physiology*.)

3. **Position** is the relation between a fixed point of the fetus and a fixed point on the maternal pelvis.

Presentation is the relation of the long axis of the fetus to the long axis of the uterus.

Rotation is the turning of the fetal head or other part whereby it is accommodated to the birth canal.

4. **PUERPERAL ECLAMPSIA.** **Symptoms:** "Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation, or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc, soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonus, etc. The fit lasts fifteen or twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions."—(King's *Manual of Obstetrics*.)

"The prophylactic treatment consists in frequent and regular examination of the urine. After the first appearance of albumin, daily quantitative examination of the urine should be made. The diet should be milk; the bowels should be kept freely open by means of calomel and salines; the skin should be kept active by hot baths, followed by vigorous rubbing. Diuretics, such as Basham's mixture, digitalis, and caffeine should be administered. During pregnancy, if the percentage of albumin increases in spite of the treatment, abortion or induction of labor is indicated.

"The treatment of the attack consists of the administration of chloroform by inhalation, chloral hydrate (gr. 60) by enema, and the fluidextract of veratrum viride hypodermically (gtt. 15 followed by gtt. 5, repeated frequently enough to keep the pulse at about 60 beats a minute), to control the convulsions, and free purgation by croton oil (gtt. 2, or 3, in sweet oil or glycerine), free sweating by the hot pack, and sometimes depletion by venesection to eliminate the poison. The after-treatment consists of free purgation by the salines, restriction of diet, and later the administration of tonics and stimulants. The obstetric treatment is usually noninterference."—(Pocket *Cyclopedia*.) Sometimes *accouchement forcé* is indicated.

5. **ECTOPIC GESTATION.** **Probable cause:** Some pathological condition in the Fallopian tube which obstructs the passage of the fecundated ovum. The most common condition is salpingitis, especially of the gonorrheal variety.

Symptoms:—"When extrauterine pregnancy exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility; nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy; pains are often very severe, with marked tenderness within the pelvis; such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating; this tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty.

(5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs*; Nos. 3 and 4 are *probable signs*; Nos. 5 and 6 are *positive signs*."—(*American Text-Book of Obstetrics*.)

Treatment consists in the removal of the product of conception by a laparotomy, as soon as the diagnosis is made.

6. *Pernicious vomiting of pregnancy.* "The treatment consists in rest in bed in a quiet, darkened room and the administration of easily digested foods, such as milk, broths, eggs, etc. A careful search must be made for some local exciting cause, and if any such condition is found, it should receive appropriate treatment. Sexual intercourse should be interdicted. The bowels should be kept freely open. Sodium bromide, camphor, cocaine, silver nitrate, cerium, oxalate, hyoscine hydrobromide, antipyrine, etc., are among the drugs used internally. Rectal alimentation may be necessary, and, as a last resort, dilatation of the cervix and internal os, or abortion may be performed."—(*Pocket Cyclopaedia*.)

7. "In *mento-posterior positions*, endeavor to secure anterior rotation of the chin when it fails to take place spontaneously. The several methods of attempting this are: 1. Press the forehead backward and upward during a pain, so as to make extension more complete, and thus cause the chin to dip lower down and touch the anterior inclined plane upon which it may glide forward. 2. Put a finger in the mouth, or on the outside of the lower jaw, and draw the chin forward during a pain. 3. Apply the straight forceps and twist the chin to the pubes. 4. Apply the vectis, or one blade of the forceps, under the most posterior cheek, and over the anterior inclined plane, thus, as it were, thickening the latter, so as to make it reach the malar bone and constitute a *point d'appui* which the chin can touch and so glide forward. Should these attempts to secure anterior rotation fail, an effort may be made with the hand, vectis, or fillet, to bring down the occiput and convert the face into a head presentation. In order to succeed in this maneuver the membranes should be unbroken, the os uteri dilated, the face not so deeply engaged that it cannot be lifted to or above the pelvic brim, and an anesthetic administered. Again, failing in this way to produce anterior rotation, the head, if it be not too deeply engaged in the pelvis, and have not passed through the os uteri, may be pushed back, and the child be delivered by podalic version. Should none of these methods be practicable and the head become impacted in the pelvis with the chin toward the sacrum, the only resort is craniotomy. Attempts have been made in these cases to deliver by forceps after lateral incision of the perineum, but they can only succeed when either the child is small or the pelvis over-large. Usually the child's life has been so far imperiled by delay and its consequences that craniotomy may be done without compunction. Possibly symphyseotomy may prove useful in these cases in future. In all cases of face presentation special care is necessary to avoid rupture of the perineum."—(*King's Manual of Obstetrics*.)

8. *Cesarean section.*—"Indications: The cases in which it is performed are: (1) Extreme deformity of the pelvis, in which delivery by forceps and version is excluded, and in which craniotomy is either impossible or would be more dangerous to the mother than cutting into the abdomen and uterus; and in which there is not room for a successful symphyseotomy. Such cases present the 'positive' indication for cesarean section; there is nothing else to be done. Flat pelvis having a conjugata vera of 2½ inches or less, and justo-minor pelvis with a conjugata vera of 2½ inches or less, present this positive indication; (2) cases of more moderate pelvic contraction in which craniotomy is possible, but cesarean section is agreed upon to *save the life of the child*; (3) mechanical obstruction in the pelvis from fibroid, cancerous, bony, or other tumors which cannot be pushed up out of the way or be safely removed; (4) irreducible impaction of a *living* child in transverse presentations; (5) in women dying near the end of pregnancy the child, if alive, is rapidly delivered by *post-mortem* cesarean section; (6) various other obstructions from inflammatory adhesions, atresia, constrictions, etc., of the vagina, and uterine displacements,

may rarely require the operation; (7) recently the operation has been done in eclampsia cases, where more conservative methods of rapid delivery were impracticable; and (8) in placenta prævia, chiefly with a view to lessen the infant mortality attending the usual treatment of this complication."—(*King's Obstetrics*.)

Cesarean section.—"Fuidextract of ergot, mxxx, is injected into the thigh muscles just as the anesthesia is begun. The operator assures himself that there is no loop of intestine between the uterus and abdominal wall, beneath the field of incision. Should a coil of intestine be found there, it is pushed above the fundus. An assistant holds the uterus in central position. The skin incision extends one-third above and two-thirds below the level of the umbilicus. It is best made through the right rectus muscle. The external layer of the rectus sheath is divided, the muscular bundles separated with handle of scalpel and the fingers, and the deep layer of the sheath and the peritoneum divided after lifting them with tissue forceps. Bleeding vessels are controlled by gauze sponge pressure or held by catch-forceps before opening the peritoneum. A short longitudinal median incision is made in the uterine wall beginning at the fundus, avoiding the membranes if still unbroken. This is extended downward with fingers, scissors, or scalpel to a total length of about six inches. The hand is thrust through the membranes and the child is extracted by the head or the feet, whichever is most accessible. In case of anterior implantation of the placenta, usually the hand may best be passed directly through it. The cord is clamped at two points with catch-forceps, cut between them, and the child is passed to an assistant. The uterus slips out of the abdomen as the child is extracted, and the intestines are kept back with hot sterilized towels placed over the upper part of the incision. The coverings help also to protect the peritoneum from soiling. The uterus is wrapped in hot moist cloths. As a rule, it is better not to wholly evert the uterus. The placenta, if not spontaneously separated, may be peeled off by grasping it with one hand like a sponge. If the cervix is not sufficiently open for drainage, a large rubber tube or gauze strip is passed down through it and withdrawn from below. Irrigating or mopping the uterine cavity is unnecessary. Asepsis is promoted by leaving it as nearly as possible untouched. The peritoneum is sponged dry with the least possible friction or handling. The uterine wound is closed with deep No. 2 chromated catgut sutures at intervals of about ¼ inch. They are given a wide sweep laterally through the muscular wall, falling short of the decidua. The peritoneal coat of the uterus is closed with a No. 1 continuous plain catgut suture, forming a welt over the deep suture line. The hemorrhage is inconsiderable and usually ceases with the introduction of the first sutures—a hypodermic of ergotole should be given before beginning the operation, and one of ergotole and pituitrin on the delivery of the child. Retraction of the uterus is ensured by manipulating it, if necessary, through a hot towel, or by faradism. When there has been much blood lost, a quart or two of warm sterilized 0.9 per cent. salt solution may be left in the peritoneum. The parietal peritoneum is closed with a plain running No. 0 catgut suture. Interrupted silkworm-gut sutures are then passed at intervals of about ¾ inch through all but the peritoneum, from within outward. The fascia is brought together with interrupted No. 2 plain catgut sutures, or with a continuous suture. The silkworm-gut sutures are now tied. The abdomen is cleansed, and the wound covered with a dressing of several thicknesses of dry sterile cheesecloth; over this is placed a thick compress of sterile absorbent cotton."—(*Polak's Obstetrics*.)

(To be concluded.)

Gangrenous Tonsillitis Cured by Antigangrenous Serum.—That ordinary gangrenous phlegmon is the same affection as gas phlegmon and gas gangrene in war wounds has been shown recently for Ludwig's "angina," and Tixier has made the same observation in a case of gangrenous tonsillitis. The local and general reactions were both severe when a mixed serum of the nefringens septic vibrio and bacillus of edema was injected in full dose into the muscles along with antistreptococcus serum. A cure promptly followed.—*La Presse Médicale*.

Miscellany.

New Swedish Marriage Law.—The leading principle of this "advanced" marriage law is "to make the position of husband and wife equal; their rights and duties mutual in every respect, and to make them both responsible for home and family" (*International Woman Suffrage News*). The guardianship of the husband is totally abolished. A wife may, like her husband, choose her own domicile, and is entitled to take her working utensils and part of the furniture. She may practise any trade or profession without her husband's consent and has all the liberty of contract even with her husband. The parents are made joint guardians of their children. The only instance where different rights are accorded is where a child possesses a fortune of its own, in which case the father is the legal trustee. If both parties to the marriage want it dissolved, they have only to send in to the proper authority an application for separation, which is then granted for one year without further investigation. When the year ends each of the parties may urge a full divorce and is not obliged to give any grounds for his or her demand. Divorce is then immediately granted. Reasons must be assigned when one or both want a divorce before the end of the year of separation, or if only one party desires separation against the wish of the other. Such reasons are mainly infidelity, desertion, debauchery and drunkenness, neglect of family duties, and knowingly exposing the other to contagion through venereal disease. When marriage is dissolved through divorce, all property in which is vested a marital right is equally divided between the parties. The court decides which of the parents shall take care of the children, and its decision is founded solely on what is best for the children themselves.—*Social Hygiene Bulletin*.

Consumption of Licorice.—It is estimated that before the World War the consumption of licorice in the United States exceeded 100,000,000 pounds annually. Practically 90 per cent. of the amount consumed is utilized in the tobacco industry, the remainder being used in the manufacture of confectionery and drugs. Practically the entire supply is imported into this country from Europe and Asia. In 1918, according to a bulletin issued by the National Bank of Commerce, imports of licorice root fell to 26,983,000 pounds, although the reduced imports were appraised at \$1,854,000, which is \$135,000 higher than the pre-war average. During the year ended June 30, 1920, China sent to this country 6,376,000 pounds of the total imports. Turkey, Russia and Southern Europe sent the rest.

Cost of Venereal Diseases to the Army.—Statistics were recently compiled upon which to base an estimate of the cost of venereal diseases to the Army show that during the calendar year from January 1, 1919, to December 31, 1919, venereal diseases in the Army caused a loss of 1,923,420 days. Since practically all of this lost time represents days spent in hospital under treatment for gonorrhea, chancroid or syphilis, and since the estimated cost of such hospitalization for each patient per day is \$7.00, it may be said that the loss to the Army caused by these diseases, measured in dollars, was \$13,463,940.—*Medico-Military Review*.

Therapeutic Hints.

Pyrexia of Dental Origin.—Captain Herbert Wallis, R. A. M. C., discussing pyrexia of dental origin which he is inclined to believe is often due to pyorrhea, recommends the following mouth application, which should be used, along with thorough scaling and syringing the gums under pressure three times daily:

℞ Vin. ipecac.....	5iij
Liq. arsen.....	5iij
Glycerin	5iij
Aquam	ad 5viii

This mixture is issued in two-drachm bottles (to obviate self-poisoning).

Three drops should be used twice daily; apply one drop at a time on the toothbrush. The gums should be gently brushed with this mixture on the brush.—*The Journal of Tropical Medicine and Hygiene*.

Scarlatina.—Hyman I. Goldstein holds that in the vast majority of cases with slight sore throat, little fever and only mild constitutional symptoms, isolation, rest in bed, diet and nursing, local care of the nasopharynx and skin, and the administration of the mixture given below, constitute all the treatment necessary.

℞ Sodii citratis.....	5iij
Syrupi	5iv
Liq. ammon, acetatis.....	
Liq. potasii citratis.....	āā q.s. ad 5iv

M. sig.: Teaspoonful in sweetened water every two or three hours.—*Journal of the Medical Society of New Jersey*.

Eczema in Infants.—Diluted citrine ointment, externally, and very small doses of arsenic internally, in the following forms, are recommended for the relief of this condition:

Ung. hydrarg. nitratis.....	drs. 3 to 5
Ung. aq. rose, q.s. ad.....	oz. 1
M. sig.: Apply twice daily.	
Liq. Potas. arsenitis.....	dr. 1
Aq. destil. q.s., ad.....	oz. 1

M. sig.: Two to eight drops once a day.—*Clinical Medicine*.

Eclampsia.—Trevor Berwyn Davies gives the following suggestions for the prevention of recurrence of the seizure in eclampsia: Absolute quiet is essential. Avoid manipulation and give sedatives. Of these morphine is by far the most important; $\frac{1}{2}$ gr. should be given; repeat two-hourly $\frac{1}{4}$ - $\frac{1}{3}$ gr. up to 2 gr. The use of chloroform has been largely given up owing to its toxic effects, and ether is the anesthetic of choice. This should be given before all manipulations.—*The Clinical Journal*.

Protein Sensitization in Eczema.—Maximilian A. Ramirez reports seventy-eight cases of eczema tested with proteins, thirty of which gave positive skin tests. Like asthma, he holds, anaphylactic eczema occurs most frequently under the age of thirty. Eczema associated with asthma or hay fever is usually anaphylactic. Only a small percentage of all cases of eczema are anaphylactic, but it is essential that patients be thoroughly tested in order that they may be properly classified and treated.—*Archives of Dermatology and Syphilology*.

REMARKS ON THE CARDIAC ARRHYTHMIAS AND THEIR IDENTIFICATION BY METHODS WHICH ARE GENER- ALLY AVAILABLE.

BY EDWARD E. CORNWALL, M.D., F.A.C.P.

BROOKLYN, N. Y.

A FEW years ago the pathological side was emphasized in cardiac diagnosis; the diagnostician strove to keep in mind the pathological pictures of what the autopsy might show; murmurs were eagerly sought for as evidences of structural changes in the heart, and signs and symptoms of mechanical failure of the heart were much regarded, especially as a basis for treatment. The pendulum has swung the other way; now it is the fashion to speak slightly of murmurs, and to make much of the physiology of the heart beat, and especially of its irregular beating. The spot light is on the arrhythmias, and murmurs, abnormal heart sounds, the mechanical effects of cardiac insufficiency, and the data revealed by the old methods of physical examination with the trained senses, are cast into relative shade. Recent literature on diseases of the heart is excessively devoted to discussion of the arrhythmias.

The reason for this extraordinary prestige of the arrhythmias is found in the revelations made by the new, brilliant, impressive and precise graphic methods of examining the heart beat, particularly with the electrocardiograph. These revelations have made the arrhythmias appear as something besides mere manifestations of irregular heart action; they give an inkling of the more intimate workings of the cardiac physiology; and in some cases they point directly to definite pathological lesions. Study of the arrhythmias in the light of these revelations has educated the medical profession not only in the identification of the irregularities themselves, but also in thinking of heart disease along physiological lines.

It is not the purpose of this paper to discuss the relative place of the arrhythmias among the data of cardiac diagnosis, nor the performances and possibilities of the electrocardiograph. It is enough to say here that the value of the arrhythmias in diagnosis is positive and definite, and that the graphic methods of examination are the most effective for their identification. The writer desires in this paper to discuss very simply and briefly the nature and significance of these arrhythmias and their identification by the methods of examination which are generally available; for it is obvious that

the electrocardiograph is not available for use in general practice; its use, in the main, must be restricted to research laboratories, to large hospitals, and to special workers.

The question immediately arises, however: How far do the ordinary methods of examination fall short of the graphic methods? How much diagnostic and therapeutic deficit must necessarily result to the average patient from failure of the attending physician to employ the electrocardiograph in examining the heart beat?

Testimony of a reassuring character in regard to the effectiveness of the ordinary methods of examination as compared with the graphic methods is given by Thomas Lewis, whose qualifications for speaking with authority on this subject are well known. He says: "There are few disorders of the heart beat which the unaided and practiced senses may not recognize." And James Mackenzie, speaking on this subject in its larger aspects, says: "We have the graphic records, and even the electrocardiograph. I am the last to decry the use of these methods, but I have little hesitation in saying that, as a means of estimating the heart's integrity and capacity and elucidating the significance of symptoms, they supply very little information."

The cardiac arrhythmias are disorders of the heart beat, abnormalities of myocardial function, contraction of the cardiac musculature which show irregularities in their time and force relations. Myocardial function, looked at broadly, appears as the whole heart beat repeating itself in regular sequence within a more or less clearly defined range of rate and force. Looked at more closely, myocardial function is found to be analyzable into certain primary functions of the heart muscle, which have been called: (1) Rhythmicity, or stimulus production, that is, the regular production in the muscle of stimulus material which is rhythmically exploded to produce cardiac contractions; (2) excitability, or capacity of the muscle to respond to a contractile stimulus, the excitability being measured by the minimal strength of the stimulus required to excite the response (and perhaps inversely by the length of the refractory period during which stimulus material is being accumulated); (3) contractility, or capacity of the muscle fiber to shorten in response to a stimulus; (4) conductivity, or capacity to transmit a stimulus; (5) tonicity, or capacity to resist stretching beyond a certain limit. The cardiac arrhythmias, as abnormalities of myocardial function, should be describable in terms of these primary functions of the heart muscle, and, to a certain extent, they can be described in such terms.

The generally accepted classification of the cardiac arrhythmias recognizes these seven fundamental

varieties: Sinus arrhythmia, or simple irregularity; heart block; premature contractions or extra systoles; paroxysmal tachycardia; auricular flutter; auricular fibrillation, and alternation of the heart.

In sinus arrhythmia there is disturbance of stimulus production in the sinus node, the normal pacemaker of the heart; influences coming to the heart from without through its nervous connections interfere in some way with the rhythmic impulses which are formed and discharged in the sinus node; and as a result an irregular sequence of contractions takes place in the heart.

In heart block conductivity is impaired or destroyed in a definite region of the myocardium, usually the auricular ventricular bridge, with the result that the passage of contractile impulses from one part of the heart to another, and usually from the auricles to the ventricles, is impeded or stopped.

Premature contractions seem to be manifestations of increased excitability, usually in some region of the heart outside of the sinus node. In normal conditions excitability and stimulus production seem to diminish in the cardiac musculature directly with removal from the sinus node, or, at least, rhythmic contractions occur naturally at a less rapid rate; which explains in a way the ability of the sinus node to maintain its supremacy as the regular pacemaker for the rhythmic heart beat. Premature contractions would indicate the temporary development of a new focus in the cardiac muscle with a higher degree of excitability than the sinus node.

In paroxysmal tachycardia there seems to be increased excitability in some region of the cardiac musculature which is of sufficiently high degree to cause the production of regular contractions of the heart at a more rapid rate than normal. The manifestations of this arrhythmia occur in paroxysms. The condition may be considered as a rapid series of extra systoles.

Auricular flutter seems to be a manifestation of abnormal physiology of the same general character as paroxysmal tachycardia, but with a defect of conductivity added to the increased excitability, which produces partial heart block; and the increase in excitability would seem to be greater and more persistent than in paroxysmal tachycardia. Lewis suggests that auricular flutter is due to a contraction wave that is started in a very sensitive region, which, owing to interferences in conduction, propagates itself in a circle, coming back to the point it started from; "when the contraction (with its accompanying refractory state) having subsided at the point stimulated, the traveling wave passes on and is continued in a movement which completes the circuit of the ring over and over again. Thus a series of contractions results from a single stimulus."

In auricular fibrillation there seems to be increased excitability and also interference with conduction. There is piecemeal contraction of small sections of the auricle which prevent it from contracting as a whole; and haphazard transmission of impulses to the ventricle, to which it can resound only with contractions absolutely irregular in time and force. Lewis suggests that fibrillation may be caused by "decreased conductivity whereby the excitation wave is broken up and travels along sinuous and varying paths, reentering fibers through which it has already traveled."

In alternation of the heart there appears to be defective contractility: the capacity of the heart muscle to recover contractile power is impaired, so that every second beat is comparatively weak; and defective excitability and conductivity may also be involved. The hypothesis has been advanced that a varying number of muscular fibers contract during systole in this condition.

The seven types of cardiac arrhythmia mentioned above may appear in combination or association; and there seems to be an especially close relationship between paroxysmal auricular tachycardia, auricular flutter and auricular fibrillation.

What diagnostic significance have these arrhythmias? To what extent can we interpret these abnormal functionings in terms of structural change? In most cases their pathological interpretation depends largely on other signs and symptoms.

Sinus arrhythmia may be said, in general, not to be a sign of organic heart disease. This arrhythmia, varying with the respiratory cycle, is often observed in apparently healthy young people; it is the common irregularity of childhood. The ordinary fainting attack occurring in apparently healthy people is usually a manifestation of this arrhythmia, caused by a sudden and prolonged interruption of the cardiac contractions, or a sudden and extreme slowing of the heart rate with an independent lowering of blood pressure. Phasic variations of the pulse, the retardations and accelerations being spread over ten or fifteen seconds, is one of the manifestations of this arrhythmia; it may accompany administration of large doses of digitalis. Irregularity of the heart action in which shorter and longer pauses occur indiscriminately may be met with in children who show no other evidences of heart disease, and in apparently healthy young adults; and it may occur in patients with rheumatic disease who are under the influence of digitalis. According to Lewis all sinus arrhythmias, with and without relation to respiration, are due to alterations in vagus tone.

Heart block regularly means a pathological change in a particular region of the myocardium, usually in the Bundle of His, which impairs or destroys its ability to transmit impulses; and the degree and persistency of the block may give some indication of the character and extent of the pathological changes. Slight changes may be made more effective in blocking the impulses by digitalis.

Premature contractions, in the absence of other signs and symptoms of heart disease, are generally considered to have no definite pathological significance, although, as Lewis says, their presence must be taken as indicating some disturbance of cardiac nutrition. They occur with increasing frequency in advancing years, and are commonly found in conditions of myocardial degeneration.

Paroxysmal tachycardia, considered as a rapid succession of extra systoles, would seem to have the same general pathological meaning as the premature contractions above mentioned. No definite anatomical lesion has been demonstrated as characteristic of this condition, although degenerative changes in the myocardium have been found in the autopsies of patients who had been subject to it. The exaggeration of excitability in some part of the myocardium outside of the pacemaker, as has been

suggested by experimental evidence, may be due to "intracellular changes induced by variations in the blood supply of the heart, which may or may not show degeneration of the myocardium."

Auricular flutter appears to be an auricular paroxysmal tachycardia of a very rapid rate. The associated heart block may conceivably be without pathological significance if the auricular contractions are too rapid for a normal degree of conductivity to permit all of them to get through to the ventricle; otherwise it must be accepted as a sign of myocardial disease or subnutrition. Auricular flutter is almost always associated with demonstrable disease of the myocardium or valves, and most of the cases occur in the latter part of life. It may generally be taken as a sign corroborative of organic heart disease, perhaps as pointing to a lesion in the muscular wall of the auricle which constitutes a focus of irritation.

Auricular fibrillation, as a haphazard jumble of contractions originating in different parts of the auricle, suggests a severe degree of nutritional disturbance of the auricular musculature; and if the condition is permanent, as it usually is, the presence of degenerative changes may be inferred. It occurs in the course of most organic diseases of the heart. The fact, experimentally demonstrated, that overdistention of the auricle may produce fibrillation, is significant in this connection, as is the clinical fact that auricular fibrillation is regularly attended with more or less cardiac insufficiency; and we know that whenever this arrhythmia manifests itself contraction of the auricle as a whole cannot take place.

Alternation of the heart is generally accepted as indicating pathological changes in the myocardium; and this arrhythmia may be produced experimentally by chemical poisons, notably digitalis. The pathological significance of alternation, which is positive in itself, is usually made clearer by other evidences of myocardial disease.

Let us now briefly review some of the main points in the identification of the cardiac arrhythmias by the ordinary methods of physical examination.

A simple irregularity of the heart action which waxes and wanes with respiration, natural or forced, can be diagnosed as sinus arrhythmia. Any irregularity occurring in young people, with normal correspondence between the radial pulse and the apex beat, and without evidence of coexisting organic heart disease, is apt to be sinus arrhythmia. A sinus arrhythmia can be abolished by anything that increases the rapidity of the heart's action, such as exercise, fever, or atropine; it regularly disappears when the heart rate is above 100 per minute.

Heart block may be suspected when the heart rate is below 60, and almost certainly identified when it is below 40. If the ventricle beats regularly between 40 and 50, a 2 to 1 heart block may be looked for, especially if the ventricular rate suddenly doubles when exercise is taken, falling back to the slow rate after rest; and any irregular ventricular rate due to partial heart block is usually temporarily relieved by exercise. A ventricular rate of 35 or less is almost certain evidence of complete heart block. Single dropped beats due to heart block can be differentiated from those due to premature contractions by the fact that failure of ventricular contractions cor-

responds with the pulse deficit; and usually from sinus arrhythmia by the absence of regular association with respiration. Pulsation of the veins of the neck at a rate twice that of the pulse at the wrist indicates a 2 to 1 heart block. The less pronounced varieties of heart block, especially the early manifestations of the irregularity, which consist in lengthening of the interval between the auricular and ventricular systoles, are not easy to recognize by the ordinary methods of examination, although, as Lewis has pointed out, there are two physical signs which suggest it. The auricular systole, which is not ordinarily audible in the contractions of the normal heart, may become audible when the interval between the contractions of the auricles and ventricles is lengthened: with a slight lengthening of the interval, a reduplication of the first sound may be heard, and with a greater lengthening, a double second sound may be heard, due to the fact that the auricular systole now falls in the early part of the ventricular diastole. And in mitral stenosis similar prolongation of the interval between the auricular and ventricular systoles may bring it about that the auricular systole, occurring in the ventricular diastole, may produce a murmur and thrill which replace the regular murmur and thrill due to the organic lesion of the valve; and such abnormally timed murmur and thrill occurring in the early or mid-diastole, suggest beginning heart block as well as mitral stenosis.

Premature contractions can be identified by noting that the absence of pulse at the wrist is not associated with a corresponding failure of ventricular contraction: the ventricular contraction, though weak and occurring early, gives a first sound, and also, if the premature contraction is forcible enough to open the semilunar valves, a second sound. If mitral systolic murmurs are regularly present, they are usually heard with the premature contraction, although diminished in intensity. Mitral presystolic murmurs are usually absent, although when the extra systole is auricular, the presystolic murmur may be replaced by a presystolic sound. Aortic murmurs may be heard only if the premature contraction opens the aortic valve.

The differentiation of auricular from ventricular premature systoles can be made by noting the length of the compensatory pauses following the premature contractions: When the extra systole is of ventricular origin the short and long pause sum up to the length of two normal pauses, and when it is of auricular origin the long or compensatory pause is imperfect, and the two sum up to less than two normal pauses.

The pulsations in the jugular vein may give a suggestive sign. In place of the two venous waves which belong to the ordinary rhythm, a single venous wave larger than usual may mark the premature contraction.

The characteristic disturbance of rhythm which gives rise to the pulsus bigeminus, in which a large pulse wave and a short pause are followed by a small wave and a long pause, and the corresponding pulsus trigeminus can be easily identified as due to premature contractions occurring every second and third beat respectively.

When the extra systoles occur frequently and at quite irregular intervals, they are not always so

easily identified, but usually some of them can be found which show the characteristic features of premature contractions, above described. This arrhythmia is rarely observed in hearts beating at a rate above 90, and it usually disappears when by exercise the heart's rate is increased; although if the exercise is made fatiguing, it may make the arrhythmia more prominent.

Paroxysmal tachycardia presents such striking phenomena that its recognition is usually easy. The sudden onset and termination, the fact that the rate changes only slightly when the patient passes from the recumbent to the upright position, and the fact that the rate is beyond the ordinary physiological range, are distinctive features. Any attack of rapid, regular heart action with a rate above 180, which begins and ends abruptly, is pretty sure to be paroxysmal tachycardia. The differential diagnosis from exophthalmic goiter can be made easily by the absence of the other signs and symptoms of that condition and the presence of the paroxysmal feature.

Auricular flutter cannot be identified by ordinary methods as easily as paroxysmal tachycardia, of which it seems to be a modification—a very rapid tachycardia with an added heart block, usually of the 2 to 1 variety—but a pulse rate between 130 and 160, mostly regular, persisting for a considerable time, occurring in an elderly person, strongly suggests this condition. A history of previous short attacks of this rapid pulse rate before the more persistent attack developed is also significant. Lewis says that if this rapid rate of ventricular contraction persists for a month the condition is almost certainly flutter. In cases where the pulse is notably irregular, exercise by quickening the heart rate usually transforms the irregular partial heart block into a regular 2 to 1 heart block.

Auricular fibrillation can usually be identified by the rapidity of the heart's action and its absolute irregularity. The ventricular rate is usually over 90, and the beats are absolutely irregular in time and force. Often the apex beats are considerably more numerous than the pulsations at the wrist, because many of the former are too feeble to send a pulse wave to the wrist. Any irregular ventricular rate above 120 is most likely to be auricular fibrillation. If the ventricular rate is slower than 90, which is comparatively rare in this condition, recognition may not be so easy; but close observation usually reveals the fact that the heart action is never quite regular; and the other signs and symptoms of organic disease of the heart, particularly mitral stenosis, are usually present to strengthen the diagnosis. Short presystolic murmurs are apt to disappear when there is fibrillation, but long, rough murmurs usually persist. When the auricle is practically paralyzed, the presystolic murmur of mitral stenosis may appear in early diastole. Auricular fibrillation can be differentiated from heart block and premature contractions with marked ventricular irregularity, by the fact that moderate exercise increases the irregularity in fibrillation and diminishes it in the other two conditions. Auricular fibrillation is also usually a permanent condition.

Alternation of the heart, except in advanced cases, cannot be recognized by digital examination

of the pulse. In the slighter degrees, however, it may sometimes be recognized by the aid of the sphygmomanometer: At the top range of blood pressure the pulse rate may be observed to be just one-half what it is at a range a few millimeters lower.

It is seen that the arrhythmias which depend on disturbances of rhythmicity and excitability possess, in general, a less serious pathological significance than those in whose complex is involved defective conductivity or contractility. Sinus arrhythmia and premature contractions seem generally to be without serious significance, while heart block, auricular flutter, auricular fibrillation and alternation of the heart suggest the presence of organic disease.

An important practical reason why the physician should cultivate skill in identifying the cardiac arrhythmias is found in the fact that among common cardiac signs and symptoms there are few which so disturb the peace of mind of the average patient as those which inform him that his heart is beating irregularly; he is prone to imagine the worst. But in a very large proportion of the cases showing an irregular heart beat there is no demonstrable organic disease of the heart; the irregularity is due to sinus arrhythmia or premature contractions. If the physician is able to identify the arrhythmia as one without definite pathological significance, he can greatly benefit his patient by assuring him of that fact.

A CONCEPT OF X-RAY PATHOLOGY.

II.—PNEUMOPATHY.

BY A. J. PACINI, M.D.

WASHINGTON, D. C.

CHIEF OF LABORATORY AND X-RAY SECTION, HOSPITAL DIVISION,
U. S. PUBLIC HEALTH SERVICE.

IN dorsoventral view, there appear on the plate two large clear areas (lung areas) separated from one another by a median shadow (cardiovascular stripe); the lung areas are bounded above and laterally by the shadows of the soft parts and the bones, and below by the two convex shadows that correspond to the two halves of the diaphragm. Ordinarily, the shadow of the right half of the diaphragm is on a higher level than that of the left half. Also, it is generally more intense. The costal grill crosses the lung areas; the anterior rib portions are more distinct than the posterior rib portions. In the upright position, often the apices of the lung are scarcely to be made out, being obliterated by the superimposed shadows cast by the arch of the first rib, and by the clavicle. It is generally advisable to study the apices apart from the remainder of the lung areas, the apices requiring usually a special technology for their elicitation.

INFLAMMATORY PNEUMOPATHIES.—These may be divided into three groups: (1) the parenchymatous pneumonias; (2) the interstitial pneumonias; (3) the "specific" pneumonias.

1. Of the parenchymatous pneumonias there will be considered lobar pneumonia, bronchopneumonia, metastatic pneumonia, pulmonary abscess, and gangrene.

Lobar Pneumonia.—Stages and x-ray pathology

in engorgement: Three clinical stages of lobar pneumonia may be distinguished, engorgement, consolidation and resolution. Engorgement follows the initial chill quite rapidly and in relatively few hours is superseded by the stage of red hepatization. It is seldom that the x-rayist obtains a plate in cases of pneumonia during the initial stage of engorgement; but when he does there is readily to be discerned in the affected lung area a diffuse increase in radiopacity involving all the gross histologic structures of the portion attacked. Thus, the finer bronchi, normally radioparent because free from cartilage, become visible owing to the accumulation within their lumen of catarrhal debris; the smaller blood vessels usually radioparent, become radiolucent; and the larger vascular structures, ordinarily radiolucent, become radiopaque, because of their increased volume of blood surcharged with chlorides. As the exudate accompanied with fibrin, leucocytes, red blood cells and exfoliated epithelium fills the individual air vesicles, the radioparent parenchyma becomes radiolucent. The x-ray picture of the stage of engorgement in pneumonia differs from unchanged lung in that in pneumonia all radioparent structures have become radiolucent, and all radiolucent structures have become radiopaque. As a rule, if only a fraction of the lung area is involved, the affected portion assumes a triangular figure on the plate; the base of the triangle at the axillary line, the apex of the triangle pointing towards the hilus of the lung. Above and below the infected tissue can be contrasted the uninvolved lung.

Stage of Consolidation: As engorgement continues, more cells and fibrin accumulate in the smaller bronchi and air spaces. In proportion as the air is displaced by the pathologic products, the radioparency approaches radiopacity, until the stage of consolidation, at first red hepatization, has replaced practically all the air with material as dense as the surrounding structures so that the entire area assumes a rather even radiopacity. The stage of consolidation manifests as a shadow, most often triangular, evenly radiopaque and therefore free from distinguishable structure.

In the consolidated area, the red cells lose their pigment, the leucocytes and exfoliated epithelium undergo fatty degeneration, the fibrin softens and disintegrates. As this autolytic liquefaction proceeds, the solids pass to the fluid state with attendant loss in volume; also, the softened exudate is gradually absorbed and may be in part expectorated; therefore, air again enters the involved portion of the lung.

Stage of Resolution: Edema still persists in the interstitial tissue, and the vessels, though to a less extent, are still somewhat engorged. Only the air vesicles, through regaining their air, have had their radiability altered; and in the stage of resolution, as the vesicles regain their air, they become radiolucent and radioparent lending a mottled "Swiss cheese" appearance to the healing area.

Associated Lesions and their x-ray Pathology: Fibrinous or serofibrinous pleurisy, usually slight, but often with voluminous exudate, commonly accompanies lobar pneumonia. This is naturally sought in the dependent spaces, the costo-diaphragmatic sulci, as an obfuscating shadow. Early in pneumonic infection, a transient paralysis of the

diaphragm on the affected side exists. Under fluoroscopic examination, one half of the diaphragm, that in the invaded hemithorax, remains motionless; the other half passing over its normal, sometimes over augmented, excursions.

Special anatomical forms of pneumonia may occur. Thus there is apical pneumonia, involving the upper lobe and attended with a high mortality. One lobe after another may become affected by insufflation or by gravitation. In insufflatory migration, the infecting organism is breathed into a new portion of the lung; in gravity migration, infectious products permeate the injured pleura separating the lobes on the same side, and a fresh infection in the newly attacked lobe begins. The x-ray demonstration of migration by gravity is typical and immediately recognized. In central pneumonia the area involved clusters around the hilus and loses its characteristically triangular form. Its general structure is identical to the usual form, and makes for ready recognition.

Abnormal terminations of lobar pneumonia include abscess of the lung, gangrene, tuberculosis, and chronic pneumonia. These will be considered in due order.

It is well to remember that lobar pneumonia is most often unilateral, the lower right lobe being usually the seat of disease.

Bronchopneumonia.—From the x-ray standpoint, and indeed, pathologically, the pathology of bronchopneumonia is identical in kind to that of lobar pneumonia which has just been discussed. There are two important differences; the manner of invasion and the distribution of the lesion.

Bronchopneumonia develops in connection with, and as an extension of, capillary bronchitis. So that the earliest changes in bronchopneumonia are registered as increased radiopacity of the finer bronchi. Normally radioparent in bronchopneumonia, these become at first radiolucent, later radiopaque. This is soon followed by a direct extension of the process from the bronchi to the contiguous parenchyma of the lung where an interstitial pneumonia develops followed by an exudative process. Delafield first urged the importance, and Osler reiterated it, of the interstitial inflammation of the bronchi and the alveolar walls as special features of bronchopneumonia.

x-ray Pathology: After the process is established, the x-ray pathology rests with a veritable peribronchial inflammation manifested by increased radiopacity of the bronchi plus an encapsulated radiopaque mantle extending into the lung tissue. At first, the radiopaque streaks, limited to the course of the bronchus, are separable from uninvaded lung. As the process develops, lung tissue included between two involved bronchial areas becomes compressed and atelectatic. Therefore, the normally radioparent lung, becoming airless through atelectatic changes, assumes a radiolucency. The peribronchial infection may spread further and become confluent in areas where the bronchi lie in close proximity. Even in this stage, difficult to differentiate clinically from the consolidation of lobar pneumonia, the x-ray pathology, resembling perfectly the necroscopic findings, reveals the unevenness of the radiopacity, an unevenness due to the confluence of areas of different age and density.

The character of bronchopneumonia exudate is distinctly less fibrinous than the exudate of lobar pneumonia; and the radiopacity of bronchopneumonia lesions is not quite as complete as the consolidation in pneumonia. Bronchopneumonia infiltration resolves in the manner of lobar pneumonia, both processes bearing every similarity on the x-ray plate. Since it is especially centered in the peribronchial surfaces, chronic interstitial pneumonitis and chronic bronchitis are apt to remain.

Veritable peribronchial intensification occurs in bronchopneumonia. There is no other condition in which peribronchial invasion is so accentuated; and there is no other condition in which peribronchial thickening should be read into an x-ray plate in mistake for bronchial thickening. It is a common error to find the phrase "some peribronchial thickening," or an equivalent, in routine reports of chest plate interpretations. Close study will show generally one of two things: That the intensified linear markings are not at all pathologic; or, if pathologic, are bronchial thickening and not peribronchial thickening.

Of course, the fact that bronchopneumonia is not often bilateral, and that it attacks infants and children rather than young adults, are factors aiding in the differential diagnosis.

Epidemic Influenza.—Entity not clearly established: There are those (Blake and Cecil) who attribute epidemic influenza to the bacillus of Pfeiffer. Others, MacCallum particularly, fail to subscribe to the thought that the Pfeiffer bacillus is the cause of this disease. Essentially, epidemic influenza is a form of pneumonia, the pathology of which is incident to the secondary invading organism. Usual secondary invading organisms are pneumococci, hemolytic streptococci, staphylococci, Friedlander's bacillus. With these, the influenza bacillus (Pfeiffer) may or may not be found; but the Pfeiffer bacillus, while it may occur together with any of the secondary invaders above mentioned, rarely occurs alone in a given epidemic influenza case. So that the x-ray pathology of epidemic influenza is the pathology of pneumonic types, according to the predominant secondary organism present in the case under study.

Influenza with Secondary Pneumococci: When the pneumococcus is the secondary invader, there occurs a confluent lobular pneumonic infiltration and consolidation. Dispersed alveoli become filled with a clot of exudate into which preserved red and white cells, organisms and fibrin, loosely agglomerated, are found.

Influenza with Secondary Staphylococci: As in pneumococcal secondary invasion, with staphylococcal secondary invasion, confluent pneumonic lobules appear. In the case of staphylococci, however, these tend to greater discreteness, assuming more an abscess form.

Influenza with Secondary Friedlander: Friedlander's bacillus causes a similar consolidation to that occasioned by the staphylococci, though with Friedlander organisms a gelatinous viscid exudate also occurs. With these three types of bacilli, the fundamental x-ray pathology of the infection is the result of an obliteration of the alveoli with radiopaque material. Usually the obliteration occurs widespread, the foci at first being somewhat scat-

tered. One or both lung areas may be involved. This scattered infiltration supersedes a primary bronchial infiltration, which bronchopathy is so acute, and the registrable x-ray changes so slight, as to escape anything but the most scrutinizing search on the plate; but the alveoli fill so rapidly that soon radiopaque flakes appear diffusely spread over the areas involved. These become more radiopaque and more numerous as the infection progresses. J. H. Selby aptly refers to the process as a "snowstorm." It is rare that the confluence assumes such completeness as to occasion an even obfuscation of an entire lung area. The whole lung area may be radiopaque, but the radiopacity rarely ever is uniformly dense as in the case with lobar pneumonia, or with pleuritic effusion. Influenza of the types above mentioned, pneumococcal, staphylococcal and Friedlander's, may induce a radiopacity which begins as a flaky mosaic, tends to confluency, and although a vast area may become radiopaque, a mottling persists that attests the character of the infiltration.

Influenza with Secondary Streptococci: In the main, hemolytic streptococci bring about a similar pathology to that just described for the other three types; but with this somewhat distinguishing addition: That in hemolytic secondary invasion, besides the flaky mosaic referred to, a general edema supervenes, and the consolidation is more confluent and extensive. Many hemolytic organisms are found in the tissue; and where these are most abundant, a liquefaction necrosis is initiated with resulting disintegration of tissue at that locus. The distinguishing x-ray dominant of streptococcal influenza arrives only after the consolidation is complete. Initially, the snow-flake storm appears. Dispersed radiopaque areas are prominent. These become more numerous and tend to confluency. The entire area is injected with edematous infiltration causing a uniform radiopaque veil to be drawn over the site. Through this veil of even density may be seen the pristine characteristics of lobular pneumonic infiltration. Influenza of the first three types may be represented for x-ray visualization as a snowstorm viewed through a clear glass window; while streptococcal influenza, from the x-ray standpoint, represents a similar snowstorm viewed through a ground-glass window.

Influenza with Pfeiffer Bacillus: It has been uncommon experience to have x-rayed cases where the influenza bacillus alone could be recovered at autopsy. In the few cases rayed, the dominant characteristic was the relative evenness of the radiopacity. In character, the radiopaque area was indistinguishable from a radiopaque infiltration caused by lobar pneumonia; but the orientation, triangular and usually confined to one lobe in lobar pneumonia, and extensive without definite geometric configuration excepting that incident to anatomical boundaries in influenza, may serve to differentiate. From the pathology at necropsy, the evenness of density is presumably due to the intense hemorrhagic infiltration incident to the infection.

At a camp, during the epidemic, a proficiency in x-ray diagnosis was attained wherein the type of secondary organisms was predicted from the x-ray appearance of the pathology. It was as usual to have the x-ray diagnosis include the probable secondary organism responsible for the infection as for the pathologist to surmise the character of the sec-

ondary organism from the gross pathology at autopsy; and a remarkable correctness, as shown by subsequent laboratory studies, fell with equal regularity both to the x-rayist and to the pathologist.

Abscess of the Lung.—Etiology: Abscess formation is not uncommon as a sequel to the deglutition and aspiration forms of lobular pneumonia, more especially influenzal pneumonia. Fundamentally, a circumscribed area of exudative pneumonia is the locus in which an abscess develops. The locus of exudative pneumonia registers as a radiopaque disc. As the exudate undergoes central disintegration, autolytic digestion is followed by a liquefaction necrosis; and a cavity is gouged out in the center of the exudative mass filled below with the products of liquefaction, above with air.

X-ray Pathology: In its typical form, the lung abscess is readily recognized. A fluid level is demonstrable which, with the shifting of the patient, assumes a surface according to the position of the chest. The x-ray test for fluid in the cavity consists, obviously, in making two plates, the first with the patient upright, the second with the patient on his side. If the suspected shadow is produced by a fluid bearing cavity, the level will move so as to remain parallel to the horizon regardless of the shift of the patient. Abscesses may be confused with tuberculosis, especially in the case of abscesses comparatively free from fluid; but with tuberculous cavities, other signs of tuberculous infection are contemporaneously present, particularly in the apices of the lungs. Most usually, abscesses are found in the basilar pulmonic fields, whereas tuberculous cavities occur with greater frequency in the apical and upper lung areas.

Lung gangrene is virtually lung abscess on a larger scale; and the x-ray pathology is in every way identical to lung abscess in character, differing only in the greater extent of anatomical distribution in the case of gangrene.

Interstitial Pneumonitis: Chronic interstitial pneumonia is as important, clinically, as chronic bronchitis. Excepting for the absence of tubercle bacilli in the sputum, and the temperature, both resemble tuberculosis and may be mistaken for it. It is sometimes impossible clinically to distinguish between chronic bronchitis and chronic interstitial pneumonitis. The x-ray pathology is distinctive; but it requires precise observation to differentiate the tubular thickenings of the chronically enlarged bronchi, and the laminar striations of inflamed and fibrous connective tissue when the smaller histologic units are involved. When the larger units are attacked, the distinction is made without difficulty.

2. SPECIFIC INFLAMMATORY PNEUMOPATHIES:
Pulmonary Tuberculosis.—Tuberculous inflammations of the lung occur in two forms; as tuberculous granulations, and as caseous pneumonia. Tuberculosis granulations are productive inflammations; caseous pneumonia, exudative. The former develops in the interstitial tissue, the latter fills the alveoli with exudate. Both arise from the same bacillus and may be present at the same time in one lung.

Etiology: The tubercle bacillus may reach the lung in various ways; by aspiration, or aerogenous infection; by the lymph channels, lymphogenous infection; or by the blood stream, hematogenous infection. In general, aside from direct inoculation

into the blood stream, there is always first, no matter what portal of entry, an involvement of the regional lymph glands.

Acute Miliary Tuberculosis.—Widespread development of miliary tubercles in the lung is often a part of general tuberculosis, even though the lesion be most marked in the lungs. The tubercles are found in the parenchyma of the lung, in the connective tissue forming the septa, along and in the walls of the bronchi and blood vessels, and in the pulmonary pleura.

The tubercles may be composed of cells with more or less fibrous stroma. Giant cells may be present. Coagulation necrosis is usual. Each individual tubercle is tiny and when first forming would escape detection under ordinary inspection if it were not for the associated exudate that usually involves the immediately adjacent air vesicles. This exudate is composed chiefly of exfoliated epithelial cells that have proliferated, serum, leucocytes, and fibrin.

In acute miliary tuberculosis, the microscopic tubercle, though composed of relatively radiopaque epithelial structure, is so small as to preclude visibility on the plate; but the stimulation by the tubercle of exudative infiltration in the immediately adjoining air vesicles makes for a radiopaque area, varying in size from 2 millimeters to 8 or 10 millimeters in diameter. Beginning acute miliary tuberculosis is evidenced then by the ubiquitous presence, in the septa, along the course of the bronchial walls and the blood vessels, of small radiopaque foci. At first, it is not the actual miliary tubercle that casts the radiopaque focus on the x-ray plate; but the exudate accumulated in the surrounding air vesicles stimulated by the tubercle. Just as the products of tubercle activity promote exudate in the surrounding air vesicles, so do they drain into the pulmonary lymphatics leading eventually to the hilus of the lungs. The lymph channels along the entire course of the draining circuit are engorged, and the glands at the hilus become at the same time pronouncedly enlarged.

X-ray Signs of Activity: Holmes and Ruggles refer to fine grayish mottlings typically present in plates of acute miliary tuberculosis. They regard this as the only sure basis for a roentgen diagnosis of active tuberculosis. Knox makes the test for deciding activity the distinctness and circumscription of the intensified markings. When, according to Knox, the markings are blurred and hazy, activity is indicated; but when the markings are prominent and distinctly circumscribed, they must result, says Knox, from an old-established fibrosis incident to a non-active lesion.

Recently, in an x-ray clinic at one of the Service Hospitals, a number of plates were read without knowledge of the clinical history of the patient from whom they were made. A supporter of the Knox contention diagnosed active tuberculosis in a number of undoubtedly tuberculous cases; but the most exacting clinical and laboratory survey could convince the clinicians that only a chronic process was present. Now, in an incipient lesion, there is always a definite amount of lymphatic and hematogenous engorgement in the infected area; and these engorged lymph and blood vessels, pursuing the bronchial course in places, alone in others, cast radiolucent to radiopaque shadows. As the lesion pro-

gresses, fibrosis ensues; and *pari passu* with fibrotic proliferation, which means advancing chronicity and inactivity, the engorgement recedes. It is possible, then, often to have no absolute change in the radiopacity of a structure as the metamorphosis from activity to inactivity proceeds; and also it is possible that the metamorphosis may be attended with a change in the reverse direction, the incipient pathological process being more radiopaque than the final chronic fibrosis. So that Knox's sign, that of indistinctness of structure, may mean one of two things—a new process, in its inception, or an old process, in its recrudescence. In the first case, it may represent pathological activity, in the second case, physiological resorption of a pathological remnant. Obviously, Holmes and Ruggles, and Knox's only sure sign of activity of tuberculous pathology, may often fail; and if this is true of the "sure" sign, what can be expected of less exact signs?

Activity, then, cannot be estimated from the *x-ray* plate alone in cases of tuberculosis for the reason that in limited infections the pathology is ushered out in the reverse order from that in which it appeared; radioparent structures become radiolucent and finally radiopaque in progressive infection, whereas radiopaque structures become radiolucent, and in instances radioparent, in the physiological extinction of a healed process.

In those cases where physiological reactions are incapable of extinguishing a chronic process, because of its peculiarly resistant fibrotic and even calcified structure, the *x-ray* evidence shows clearly the infection, but in no way does it give a clue as to the presence or absence of disease. Activity means disease, and disease is a purely subjective reaction. The *x-ray*ist can detect infection; he may outline it with an anatomical precision far excelling the accuracy of clinical determinations; but there is yet no sure sign advanced that is positively diagnostic, from *x-ray* evidence alone, of tubercular disease. Activity may be inferred, if the history and the clinical findings in the case are known. Purely from the standpoint of *x-ray* pathology, however, activity cannot certainly be surmised.

CHRONIC PULMONARY TUBERCULOSIS: Beginning usually in the apices, chronic pulmonary tuberculosis extends gradually to the lower portions of the lungs, and to the pleura. It heals with induration in some places, extending, or softening, in others. There are reasons why chronic pulmonary tuberculosis should choose the apices for its invading march; (1) the minimal energy of the movement of the air during respiration; (2) the lessened energy of the lymph current (according to Tendeloo) in the apex; (3) the predisposing influence of stenosis of the upper aperture of the thorax in persons of the habitus phtisicus due to a congenital shortening of the cartilage of the first rib (Freund); (4) the groove like constriction, owing to the first rib shortening, of the apex of the lung (Schmore); (5) faulty development of the bronchial tree in the apex (Birch-Hirschfeld).

X-RAY PATHOLOGY: When the apex becomes a nest for tubercle bacilli, and these begin to proliferate, the toxins reach the lymph vessels which become engorged. Radioparent lymph vessels become radiolucent, and radiolucent channels become radiopaque. The general distribution of bronchi, blood and

lymph-vessels is everywhere similar in the lung area. The larger structures are at the root and hilus; from these tree-like branching occurs, each branch being of smaller diameter and lesser caliber than the main stem from which it is derived. At the root, the larger bronchus from the tracheal bifurcation is the inlet and outlet to all the myriad bronchial structures in the lung; so that, for the entire lung, as for any particular area, the general arrangement is tree-like, the branches extending away from the hilus of the lung, toward the periphery, and the main stem extending toward the hilus.

When the tubercle bacillus lodges in the apex, the blood and lymph vessels become engorged as the first step in the inflammatory process. Since their distribution is tree-like, a radiopaque tree-like structure appears in the apex that should normally be clear.

DISTINCTIVENESS OF INCIPIENT TUBERCULOUS LESIONS: True, the apex is deficient in bronchial structure, but it is not entirely free from bronchial structure. Care must be used not to confuse the normal markings in the apex for the pathological markings due to infection. There are two criteria that make for differentiation. First, the comparison of one apex with the other. This relative standard is not always sufficient, for both apices may be infected at the same time. Secondly, the tubercle bacillus, as was pointed out in the discussion of miliary tuberculosis, incites an exudative infiltration of the adjoining air vesicles.

In the miliary type of tuberculosis, there being foci of bacillary activity everywhere present in a given locus, the air cells fill with fibrin, blood serum and particularly exfoliated epithelium; all materials that are radiopaque. In incipient pulmonary tuberculosis, there being infinitely less bacilli, the air vesicles do not become filled with exfoliated epithelium, but only with fluid; so that the tissue does not become radiopaque, but radiolucent. All the air vesicles included in the area drained by the radiopaque arborization are infiltrated with fluid, and the normally radioparent lung acquires the appearance frequently described as "filmy," or radiolucent.

This is the typical lesion of apical infection—a V-shaped radiolucent lung area ribbed with radiopaque vessels and bronchi, the Dunham fan.

LOCATION OF FAN DECIDES DIAGNOSIS: It is not the character of the fan that is diagnostic of tuberculosis. It is the location of the fan. Laboratory cultures of certain organisms, listed below, were injected hypodermatically into the apex of one lung of guinea pigs. There were: Staphylococci (aureus), Streptococci, Influenza, Meningococci, Diphtheria. The lung areas of the pigs were rayed before injection, immediately following injection, and at intervals of 30 minutes after injection until recognizable lesions had developed. The experiments were repeated with the injections made along the periphery of the lung other than at the apex. In all cases, whether in the apex or at the periphery, there develops for every organism a radiolucent fan-shaped density in the peripheral parenchyma, whether in the apex or elsewhere in the lung area. As the infection progressed it assumed more characteristic forms depending upon the organism. The important observation in connection with the experiments is the fact that in incipient stages of infection all of

the organisms used produce a similar pathology; the only difference developed in the time required to produce the pathology and in the subsequent orientation that it assumed after infection had become better established.

In a limited way the same observation holds for humans. Incipient pneumopathies of whatever origin may be shown to have foci of infection whose pathology is identical to that of the Dunham fan. The absolute significance of the Dunham fan then is that it represents a locus of edema, which locus is partly the result of a filling of the air vesicles with fluid incident to a toxemia produced by an incipient infection. There is nothing characteristic of the Dunham fan, obviously, suggestive of tuberculosis excepting its location. The fan represents incipient infection; and when it occurs in the apex or at the periphery of the lung, it generally signifies tuberculous infection. It is usual for infections other than tuberculosis not to be so discreetly localized; and their progress is generally rapid, compared to tuberculosis, so that wide spread infection is soon manifest.

HILUS ADENOPATHY: As the lymphatics drain the toxic effluents from an infected area, and the effluents reach the cluster of glands at the hilus of the lung, with all infections and lymphadenoid irritants, there is produced an enlargement of the hilus glands. Hilus adenopathy is therefore not specifically significant of tuberculosis infection. It is sometimes an index of the acuity of infection. That is, an infiltration in the lung areas that resembles one produced by tuberculosis, might be inferred to result from an active acute infection if the hilus glands are enlarged. But this X-ray sign of active infection in tuberculosis is not specific, neither is it trustworthy. In pneumoconiosis, for example, hilus adenopathy becomes chronic and persistent; so that a superadded infection in a case of pneumoconiosis, the enlargement of the hilus glands could not be interpreted as acute infection unless pneumoconiosis were first ruled out.

PROGRESS OF INFECTION: There are x-ray signs of the progress of infection which can be gathered from serial x-ray studies of a case. The signs are those of an increase in the anatomical distribution of the x-ray markings. They refer only to the registrable quantitative alterations in the anatomic distribution of the infection; and while activity is inferred by these signs, it cannot be positively stated that activity actually exists.

BIRCH-HIRSCHFELD FOCUS OF INCIPIENT TUBERCULOSIS: It is stated that in the lung the first lesion is commonly, though by no means always, in the walls of the bronchus, a centimeter or more below the apex. Birch-Hirschfeld demonstrated the formation of a tuberculous granulation tissue in the wall of the bronchus in the apical or subapical lesion. Accordingly, the peribronchial lymphatics would be involved in the draining of the infectious toxins; so that a peribronchitis would be manifest on the plate. This same process of peribronchial invasion may invade the entire lung area. The repeated stimulation and irritation occasioned by the tuberculosis toxins may induce fibrotic proliferation and occasion marked bronchial accentuation throughout the invaded lung area. It is rare to find an active progressive tubercular process relegated entirely to

the peribronchial tissues, without, at the same time, finding some foci of parenchymal infiltration; but in a cleared infection, accentuated bronchial markings incident to the fibrosis induced by the previous tuberculous infection, may remain as the only evidence of a past lung infection. In this case, the lesion truly represents a chronic bronchitis and is in no way different from the residual chronic bronchitis incident to whatever pneumopathy of toxic origin. So that thickening of the bronchial markings so often referred to in x-ray reports as peribronchial thickening, unless other signs characteristic of the infection inducing the peribronchial thickening are present, can be interpreted only as chronic bronchitis.

FIRST STAGE OR INCIPIENT TUBERCULOSIS: Excluding miliary tuberculosis and caseous pneumonia, the chronic forms of pulmonary tuberculosis may be divided into three stages, according to the extent and progress of anatomical infection.

Stage I. Initial, incipient, or developmental.

Stage II. Well established infiltration.

Stage III. Necrosis and repair, often terminal.

In general, these three stages agree with the nomenclature advanced and adopted by the National Association for Study and Prevention of Tuberculosis in which fourfold classification there are included: Incipient tuberculosis. Moderately advanced tuberculosis. Fully advanced tuberculosis. Miliary tuberculosis. The National Association classification is a clinical one and is made on the basis of physical findings and subjective symptoms.

An x-ray classification into these classes is scientifically improbable for the reason that in the x-ray study only the anatomical extent of the infection can be estimated. Practically, however, there is a close agreement between the extent of infection, and the symptoms incident to that extent, so that a useful classification of infection from the x-ray viewpoint can be made into three stages:

Stage I. Corresponding to incipient tuberculosis.

Stage II. Corresponding to moderately advanced tuberculosis.

Stage III. Corresponding to fully advanced tuberculosis.

From an x-ray standpoint a tuberculous infection that shows only an occasional film described as the Dunham fan would be classified as a Stage I infection. In so reporting the clinician would be advised that the character of infection noted on the x-ray plate was significant of tuberculosis, and that its extent was slight.

STAGE TWO OR MODERATELY ADVANCED INFECTION: When more than the apex is involved, the infiltration is more extensive than that characterizing Stage I, and in the mottling there is very little evidence of cavity formation, the infection could be termed moderately advanced or Stage II. An arbitrary limit of one-sixth of the total area of one lung might well be set as a maximum amount of infiltration that could be called moderately advanced.

STAGE THREE OR FAR ADVANCED INFECTION: When the infected area amounts to more than one-sixth of the total area of one lung the case could be reported as far advanced or Stage III. In such cases areas of disseminated cavity formation, foci of caseation and necrosis, and other anatomical complications could be descriptively included in the report.

In this manner the x-rayist has a guide for the report of tuberculous infection, which guide corresponds with sufficient accuracy to the classification of chronic pulmonary tuberculosis so as to make for an exact understanding common to the x-rayist and clinician. It is better that the infection, after it is identified as tuberculous, be reported in terms of stages, as Stages I, II or III, rather than in terms of incipient, moderately advanced, or far advanced. A Stage I infection corresponds in anatomical extent to an incipient infection; but when the word incipient is used it conveys the tacitly understood meaning of activity. If Stage I infection is used it describes accurately the anatomical extent of invasion without specifying activity or inactivity, both of which are more for the clinician than for the x-rayist to determine.

ACUTE FORM OF PULMONARY TUBERCULOSIS: Barker refers to the acute form of pulmonary tuberculosis as *phthisis florida* or galloping consumption, and includes in the classification the pneumonic form and the multiple focal form.

In the pneumonic form, including caseous pneumonia, the infiltration is similar to the infiltration incident to moderately and far advanced chronic forms. It differs only in that in the pneumonic form the infiltration is more massive, thereby more closely resembling lobar pneumonia, and progresses with great activity.

The focal form may be disseminated, hemoptoic, or peribronchitic. The conditions are rapidly recognizable on the x-ray plate. It is indeed more difficult clearly to recognize a diagnosis of Stage I tuberculosis, from x-ray evidence, than it is to recognize a diagnosis of any other stage of tuberculosis.

GENERAL CONSIDERATIONS: In certain instructions under the title "Principles of X-Ray Diagnosis" issued to Roentgenologists in the Hospital Division of the Public Health Service, the following general considerations were included:

Abnormal densities at the hilum need little description unless they are markedly abnormal or connected to a parenchymal lesion by a heavy trunk. Calcified areas at the hilum and even in the lung tissue, indicate resistance to tuberculosis rather than pathology of clinical significance.

Peribronchial thickening unless very pronounced or much heavier within one lobe, should receive limited consideration. The bronchi to the bases are normally heavy and unless connected to the pleura by abnormal densities should not receive consideration except in cases giving a history of gas, bronchiectasis or having signs of emphysema. The trachea, aorta and heart should be noted, and if dislocated it should be stated in which direction.

Abnormal densities, such as faint cloud-like "fans" are often artificially produced by improper technique, such as breathing between stereoscopic exposures or a too long exposure. Stereoscopic plates are necessary to determine the location of an abnormal density within the lung.

Decreased densities within bronchi on end, and outside the pectoral muscle are normal and are to be disregarded. Such areas surrounded by studied or mottled increased densities should be classified as tuberculous until other etiology can be proved.

SYPHILIS OF THE LUNG: Syphilis of the lung is very similar in its x-ray pathology to pulmonary tuberculosis. It may assume a gummatous form, in which discrete rounded areas of radiopacity are scattered through the lung field; but more often assumes the form of a chronic, sclerotic, interstitial pneumonia. There are three x-ray indications of

the specificity of the lesion. First, whether the discrete or the sclerotic form is present, the pathology in each case favors clustering in the region of the hilus; and, unlike tuberculosis, rarely, if ever, invades the apex. Secondly, the lesions are as a rule of great extent and wholly out of proportion to the few clinical symptoms of the case. Third, after specific therapy, whether by salvarsan or mercury, the pulmonary lesions can be seen to retrogress in serial x-ray plates.

PNEUMOPATHY CHARACTERIZED BY CHANGES IN THE ALVEOLAR LUMEN: There are two principal pneumopathies that follow under this grouping. The first is atelectasis; the second, emphysema. Atelectasis is recognized best by the pneumothorax-like condition that accompanies an atelectatic lung. There is nothing particularly distinctive about a collapsed lung, whether the collapse is due to the atelectasis of the new-born or is of acquired origin. The x-ray diagnosis depends on the accompanying removal of lung tissue from those parts of the normal lung area from which the collapsed lung has shrunk.

In emphysema there is an abnormal inflation and dilation of the air cells. The abnormality may be temporary; but is more commonly permanent. Five clinical forms are recognized. These are: Chronic hypertrophic; atrophic; acute vesicular; interstitial; and compensatory.

CHRONIC HYPERTROPHIC EMPHYSEMA: This is distinguished from other forms of emphysema not by the character of x-ray pathology, which is similar in all types, but by the distribution of the lesions. In chronic hypertrophic emphysema both lung areas are involved more or less uniformly, and in most cases the greatest amount of inflation involves the apices. The shape of the costal grill, which assumes a barrel form, is often of x-ray importance in pointing to the possibility of the presence of a chronic hypertrophic emphysema. There may be isolated areas of pneumothorax. The bronchi throughout both lung areas may show an intensity in their markings representing a chronic bronchitis usually associated with emphysema. Occasionally, dilated bronchi, tending to bronchiectasis, occur.

Acute vesicular emphysema is less extensive than the chronic form and occurs usually as the sequel to some bronchial infection or to any condition that throws violent respiratory effort on the lung structures. Because of its secondary character it is seldom of x-ray pathological interest; there being in the same plate much more clinically important pathology which attracts the interest of the roentgenologist.

Interstitial emphysema is characterized by the formation of large bullae in the interlobular and subpleural tissues. Rupture of one of these large bullae near the root of the lung leads to an extravasation of air along the trachea, and thence into the subcutaneous tissues of the neck. The x-ray pathology in this form of emphysema is characteristic, the lung area representing the usual emphysematous appearance, and in addition there is an air infiltration of the soft tissues overlying the clavicular space.

Whatever the cause of emphysema, the air super-inflated lung makes for abnormal clearness or radioparency of the otherwise radiolucent parenchyma.

This abnormal clearness is often associated with a protusion to the right of the cardiovascular stripe.

PNEUMOPATHIES OF CIRCULATORY ORIGIN: There are included under this heading: (A) Chronic passive congestion of the lungs and stasis bronchitis. (B) Pulmonary hemorrhage and hemoptysis. (C) Pulmonary embolism, hemorrhagic infarction of the lung and thrombosis of the pulmonary artery. (D) Edema of the lungs.

Of these, edema of the lungs is of possible x-ray interest. It may be due to an inflammatory etiology as in pneumonia; or a non-inflammatory origin as in cardiopathy. When due to pneumonia the associated pathology is of a distinguishing character; and when due to cardiopathy it might better be considered under the classification of heart disease.

PNEUMOPATHY DUE TO FOREIGN BODIES AND PARASITES: Two general heads are included under this title, the pneumoconioses and parasitic invasion of the lung. The x-ray diagnosis of a pneumoconiosis depends upon the chronic bronchitis, the interstitial inflammation and the characteristic radiopacity due to the particular pneumoconia. There are three main varieties of pneumoconioses that are distinguishable, namely:

"(1) Anthracosis pulmonum, due to carbon or coal-dust, met with in coal-miners, chimney-sweeps, stokers, and workers in graphite.

"(2) Calcicosis pulmonum, due to stone-dust, and met with in stone-cutters, slate-workers, polishers, etc. The gold-miner's phthisis of South Africa seems to belong here.

"(3) Siderosis pulmonum, due to iron-oxide-dust, met with in file workers, iron-workers, scissors-grinders, mirror-makers, workers in wall-paper factories, etc." (Barker).

The lung dust responsible for the lesion is exceedingly radiopaque and shows pronouncedly on the plate. Under parasites of the lung, the x-rayist occasionally meets with invasions by actinomycetes. In this infection the x-ray pathology assumes the form of lung abscess. The diagnosis is made in the laboratory rather than by the x-rayist.

NEOPLASTIC PNEUMONOPATHIES: Neoplastic invasions of the lung may effect primarily the lung substance or the bronchi, as in carcinoma; or are brought to the lung metastatically through the blood stream, as sarcoma, or reach the lung directly by extension from a primary invasion from the mediastinal structures.

Carcinoma of the lung may originate at the hilus. There is nothing pathognomonically characteristic of hilus malignancy. In a certain type it may be disseminated throughout one or both lung areas in the form of discrete scattered foci. The origin of these foci may be that of a blood dissemination of malignant nuclei throughout the lung field; and, as the nucleus arrives in its newly deposited locus, a malignant growth proceeds. This epithelial growth is radiopaque; so that the x-ray pathology of metastatic malignancy approaches the appearance of a miliary tuberculosis, from which it differs in that in malignancy each locus is larger than in miliary tuberculosis, is more discrete and more radiopaque.

Another form is described in which radiopaque plaques are scattered throughout the lung field. This is a relatively uncommon form of metastatic malignancy.

Primary malignancy is rare. It is most always unilateral and may be nodular or infiltrating. When nodular the lesions gather around the hilus. When infiltrating the lesions follow the bronchial distribution from whence it arrives.

Says the U. S. Army X-Ray Manual, in connection with new growths of the lungs:

Of metastatic new growths those most commonly encountered are carcinoma and sarcoma. By means of the x-ray examination alone it is not possible to distinguish them. The earliest metastases appear as faint circular homogeneous shadows a few millimeters in diameter. They are irregularly distributed throughout the lungs and are larger in the lower lobes. The size they attain varies with the type of the primary tumor and the duration of the disease. They may attain the size of a lobe; on the other hand, even at a late stage of the disease the lungs may be studded with myriads of small metastases. Miliary carcinosis may be difficult to differentiate from some forms of tuberculosis. The x-ray examination will reveal metastases before the clinical examination will discover them. For this reason it is important to ray the chest prior to operation of primary tumor, especially sarcoma, in other parts of the body.

Primary new growths occur in two forms, the true pulmonary and the mediastinal tumors. By the x-ray examination, just as by the clinical, it is often impossible to decide whether a neoplasm arises in the lung or mediastinum, because mediastinal growths as they increase in size may invade the lung. In their earlier stage this distinction may be made.

Primary carcinoma of the lung assumes two forms, the so-called bronchial carcinoma and the lobar carcinoma. The former begins usually in one of the larger bronchi and casts a dense shadow extending a variable distance from the root of the lung. Numerous secondary tumors develop by extension along the bronchial system, producing a network of small shadows along the bronchial tree. In lobar carcinoma there is found a dense shadow which occupies a part or all of a lobe. This seems to occur more frequently in the upper lobes. In all forms of primary growths the intercostal spaces are frequently narrowed, and the heart and mediastinum are apt to be drawn over to the affected side, unless prevented by a hydrothorax.

INSOMNIA.

By C. E. PEARSON, M.D.,

CATONSVILLE, MD.

INSOMNIA means no sleep. In practice it means that the afflicted one is a poor sleeper. The quantity of sleep is diminished. Although the word insomnia does not suggest it, in a study of this kind we should include also those cases where the quality of the sleep is not normal. In many cases both conditions prevail. No one can do without sleep for a protracted length of time.

In the beginning insomnia is usually nothing more than a symptom. However, I have reason to believe that it often becomes in time the predominate factor of an abnormal condition. It is a part of my purpose in this article to show how this may happen. When one becomes a poor sleeper it is a serious matter. It lessens efficiency and diminishes the enjoyment of life.

Chronic insomnia demands serious study. The physical factors that cause insomnia and also the physical factors that prolong insomnia, are matters of great importance. The discussion of these factors, however, I will leave to the surgeon and to the internist. In this article I shall confine myself to a study of the psychic elements of the trouble, considering: 1. Psychic factors that have to do with the

passage from the waking to the sleeping state. 2. Psychic factors that aggravate and prolong insomnia. 3. Psychic factors that act as a first cause. I have read many learned and interesting studies as to what the sleeping state really is; I am sorry, but I am still in ignorance.

Fatigue if great enough will bring on sleep. This is an important fact, but not of much practical value. It is important that we pass from the waking to the sleeping state at the proper hour whether we are fatigued or not.

Let us look in at the family circle of the average American family during the evening hours. Perhaps the family are playing cards. The conversation is animated. There is no evidence of either drowsiness or fatigue. But when father glances at the clock and perceives that the hour for retiring has arrived, when he arises and begins to wind the clock, each member of the family begins to show unmistakable signs of drowsiness. Does this mean that each one in the family has become suddenly fatigued? I hardly think this even a possible explanation.

No, this is an average family of normal habits. Their lives are well ordered. They have a regular hour for retiring. Certain impressions and suggestions connected with this hour are registered in the subconscious brain of each member of the family. These suggestions and impressions have been doing their good work over a long period of time. Their regularity and long continuance is at last sufficient to hypnotize automatically each member of the family into the condition we call sleep.

We often hear the remark "I am so dead-tired that when bed-time comes, I drop asleep as soon as my head touches the pillow." But if we look into the history of the case we do not discover that the work done by this particular person is of a very strenuous character. The real truth is, I think, that the impressions and suggestions concerned with the transitional period between waking and sleeping are so wholesome and so thoroughly normal that this individual is actually compelled to go to sleep through autosuggestion.

Sleep itself can hardly be called a habit. The ability to drop asleep at a certain hour is a habit. It is about the best habit I know. Where the psychic features predominate, insomnia may really mean nothing more than the loss of this excellent habit. Many people have had the habit of dropping asleep at a certain hour so long that they suppose they were born that way. They were not. The baby is not the least bit particular about his hour for dropping asleep. Neither is he at all particular about those hours that he proposes to devote to wakefulness. Many fond parents who have walked the floor at night with a wakeful baby in their arms are well aware of this fact. The savage, who can not appreciate the civilized man's blessed privilege of working like a slave, is not much more particular than the baby about his hours for sleep. Any time when he has nothing more important to do seems to answer very well. Our colored brethren who have been learning our ways now for a long time do not seem as yet to have developed any great need of being especially solicitous about any certain hour of the twenty-four for passing into the sleeping state. Even with many of us the mere thought of an oppor-

tunity to take a nap seems to carry enough of autosuggestion with it to enable one to pass at once from the waking to the sleeping state.

Times and conditions may change with us. One who can pass from the waking to the sleeping state almost at will may himself at some future time become the victim of insomnia. Civilization is becoming more complex. The percentage of families who can have one certain hour for retiring for all the members of the family is becoming less. Father works during the ordinary daylight hours. George quits work at 11 P.M. and cannot retire before midnight. Mother has to see to it that he has a warm supper before retiring. John goes on duty at 4 A.M. and must have an early hour for retiring. Sammy works all night and must sleep as best he can during the day. It is surprising how well really healthy people can accommodate themselves to such circumstances. In spite of unfavorable conditions they retain in the subconscious brain the normal psychic impressions connected with the passing from the waking to the sleeping state.

These psychic impressions naturally vary under different circumstances. Some city people need the monotonous roar of the street traffic in order to pass easily from waking to sleeping. The uncanny stillness of the country, the absence of the street lights, the creaking of the crickets and the katydids, the distant hoot of an owl, the croaking of the frogs drive many city people almost to distraction. The countryman in spite of his rugged health is distressed and wakeful from the roar of the city noises at night. Many trainmen can sleep better in the swaying noisy little red caboose than they can under what would seem to be more favorable circumstances in their own homes. Most people can sleep very well in spite of the stress of modern civilization. Others who inherit irritable nervous systems can not retain correct habits of sleep on account of the rapid changes in environment, in occupation and in a thousand and one ways. In their cases the normal psychic impressions that should go with the transitional period from sleeping to waking become obscured. They may become poor sleepers without any tangible first physical cause. Where the inherited neuropathic tendency is pronounced they may not only become poor sleepers through the above named causes; they may even become insane. Whereas if they had been surrounded by the influences of a more simple life; and if they had been able to have one unchanging hour for retiring every night, they might have been able to pass through life successfully and normally in spite of developing inherited neuropathic tendencies.

Nothing succeeds so well as success. This is as true of sleep as it is of anything else. When one has enjoyed successful sleep night after night over a long period of years the impressions registered in the unconscious brain become stronger and more sleep compelling as the years go by. Failure of any sort leaves behind a whole train of irritating and unwholesome impressions registered in the unconscious brain. It is an old saying that "failure begets failure." Our identity does not consist in the length of our noses or in the confirmation of any of our features. It is our memories, both conscious and subconscious, that give to each one of us our personal and particular place in the universe.

These things have a great deal to do with making or breaking us. The painful impressions recorded in the brain because of hundreds of nights of poor sleep or no sleep constitute a force for ill of no mean power. While this force can not be said to be just so long, just so high, just so wide: and while it can not be declared to weigh just so much, its ponderability and magnitude for harm are very real indeed.

I now come to a study of certain psychic factors that may prolong insomnia or that may be the means of continuing the insomnia long after the physical causes have ceased to be operative.

Among the physical causes of insomnia of course are included all painful diseases or traumatism. Anything that may cause reflex disturbances like indigestion, faulty metabolism, alcoholism, etc.

In most cases after the internist or the surgeon has removed the physical causes the patient soon gets back into normal habits of sleep. Where insomnia accompanies painful diseases, it is only a symptom. However if these disturbances last over a long period of time, we can readily see how there may be superimposed upon the normal physis impressions connected with the transitional period between waking and sleeping a whole series of painful impressions and unwholesome suggestions which may nullify to a great extent the sleep compelling power of the normal suggestions.

If the individual inherits psychopathic tendencies, a very moderate amount of physical suffering may be sufficient to break up and destroy to a large extent the sleep inducing power of those suggestions registered in the brain previous to the patient's illness.

In cases of this sort insomnia may cease to be a mere symptom and may become the dominant factor. Even in cases where the patient has inherited a robust constitution, a series of painful diseases or accidents or other factors that may interfere with sleep may so completely break up wholesome suggestions that the first causes may pretty much disappear and insomnia may cease to be a mere disagreeable symptom and become the principal feature of the illness. Of course in no case of insomnia can this feature be said to be the only factor. Because insomnia itself reacts to produce a lowered resistance and a marked depreciation of the vital powers. What I mean is that the insomnia may cease to be a mere symptom or result of the diseased condition and may become the main cause of the patient's enfeebled health.

I realize of course that the physical debility that must remain after a long series of illnesses or accidents must react to interfere with sleep. However, I believe that the psychic elements are the more important of the two. Both physical and psychic elements are present in every conceivable condition of both health and disease. It is only a question of relative importance. To my mind the psychic elements in these cases are the more important.

We might naturally suppose that painful conditions lasting over a long period of time are the most effectual means of breaking up the autohypnotic power of the impressions registered in the subconscious brain concerning the period just preceding sleep. I do not believe that this is the case. The long continued use of any one of the hypnotics to in-

duce sleep will more effectually obliterate normal psychic suggestions than any pain can do.

Every time a person passes from the waking state to a state of artificial sleep or more properly narcosis, certain impressions are registered in the subconscious brain. These impressions are totally different from those that we get from the period just preceding normal sleep. The abnormal impressions in time will completely destroy the autohypnotic power of the previous normal impressions. It is thought by many that an abnormal craving for the hypnotic is established and that it is this craving for the hypnotic that keeps the patient awake when the hypnotic is withdrawn. This is never the case unless some form of opium is used as a hypnotic. My long experience in caring for the various drug addictions has made me very familiar with this feature of insomnia. Opium is not ordinarily a good hypnotic. However it will put the patient in a condition where he is not the least bit concerned as to whether he sleeps or not.

Any claim made in regard to any drug that it will induce or compel normal sleep is an absolute absurdity. Normal sleep is normal sleep and any other kind is not normal sleep.

The great care that many physicians take to skip from one hypnotic to another with the laudable intention of preventing the danger of inducing an addiction is to my mind a ridiculous waste of effort. The danger is not in forming an addiction but in putting the patient into a condition of chronic insomnia. This can be done and has been done just as effectually with several hypnotics as it has been done with one.

I think what happens is the abolishing of nature's method of inducing sleep by autosuggestion. This happens because the suggestions that obtain with the passing into stupor and into sleep are entirely different. When this happens there is to my way of thinking nothing left to do but to train the patient back into normal and to keep the patient sleeping normally every night over a long period of time to enable normal impressions to obscure and to obliterate the abnormal ones received from the repeated narcosis.

I now pass to a consideration of those causes of insomnia that are purely psychic rather than physical. That is to say certain emotional states: Fright, shock, grief, anger, financial losses, great mental strain, and sometimes the loss of mental equilibrium caused by overpowering success, especially sudden success followed by equally sudden failure. To those who inherit good health and whose life and environment has been conducive to the conservation and even to increasing their good inheritance, the above named causes are not likely to bring on chronic insomnia. Troubles, unless great in amount and continued over a long period of time, make about as little impression upon those in robust health as water upon a duck's back. Unfortunately not everyone enjoys good health. The constant wail of Mrs. Gummidge was that "everything goes contrary with me." Mr. Dickens also says of this character that, after living in the bright sunshine of Australia, "thinks no longer went contrary with her." However, although Mr. Dickens is silent upon this point, I fancy that Mrs. Gummidge was not a bad sleeper. Persons who worry over trifles usually

sleep fairly well. It is those troubles that strike at the very foundations of our happiness that insist upon going to bed with us.

The inventor may be so engrossed with some problem almost solved, but not quite, that he is unable to dismiss it when he retires for the night. The very intensity of these thoughts may be so great as to render inoperative the autohypnotic power of impressions registered in the subconscious brain connected with the passing from the waking to the sleeping state. This may also be true of any of the great problems of life. The greatest possible mental concentration, however, will not cause insomnia providing it is properly done.

There should be a period of diversion between the hours given up to mental concentration and the hour for retiring. A wise use of the brain strengthens this organ. Some people try to work the brain without the use of a governor belt. Some untrained and undisciplined people may get to thinking so intensely upon some problem that seems to them to be of great importance, that the brain keeps right on at the same subject against their will. Some very bad cases of insomnia arise in this way. Intense emotional disturbances take hold of the brain and refuse to let go in the same way. The resulting insomnia may be very grave. I think, however, that the insomnia is produced in both cases in the same manner. That is, the subconscious memories connected with the presleeping state become so obscured as to be inoperative.

Sleep poor in quality is often due to reflex disturbances arising from abnormal functional trouble in some part of the body. Disturbances in the alimentary tract furnish a familiar example. Sub-acute pain or distress in any part of the body which is not sufficient to keep one awake may be sufficient to cause disturbed non-refreshing sleep. Such disturbances may cause sleep that is accompanied by horrible dreams.

It has been claimed by some that powerful emotional states may cause disturbed sleep long after the original emotional disturbance has been forgotten. It is claimed that although the memory of such upsets may have passed from the conscious brain they are still present in the subconscious brain and continue to make sleep unrefreshing by causing frightful dreams. I have seen no cases of this sort, so far as I know.

Sleep may be abridged as well by a too early awakening as by difficulty in passing from the waking to the sleeping state. The causes of this trouble seem to be obscure. Nearly all the cases of this kind that I have met either were or had been heavy consumers of the distilled liquors. Whether the alcohol was the cause or not I do not know. I have never found the trouble to be very amenable to treatment.

I shall not say very much as to treatment. In cases where there is an obvious physical cause the treatment suggests itself. Mild cases of any sort can usually be treated successfully in their own homes. In all cases that show any disposition to be chronic I have only to mention the hypnotics to condemn their use in toto. If I have interpreted the matter correctly, any therapeutic measure that compels sleep or, to speak more correctly, that induces stupor, is to be condemned because it in-

terferes with nature's process. Severe cases can best be managed in a sanitarium, where the patient's habits of life can be observed and if need be corrected. If the ability to drop asleep at a certain hour is, as I think, largely a habit, then the patient should be trained back into that wholesome habit. Remedies that predispose to sleep may be used to good advantage. Anything that will assist in restoring nature's process of passing from the waking to the sleeping state, may be correctly called good therapeutics.

SOME INTERESTING THINGS ABOUT TUBERCULOSIS.*

By S. A. SLATER, A.B., M.D.,
WORTHINGTON, MINN.

SUPERINTENDENT SOUTHWESTERN MINNESOTA SANATORIUM.

TUBERCULOSIS, the most common and one of the oldest diseases of which we have any record, has been looked upon until recently as incurable and uninteresting, which no doubt accounts for the little progress that has been made in conquering it. It has been considered an inherited disease, and even now this antiquated and unscientific idea lurks in the minds of some. It has, however, been clearly proven that it is not inherited, but that the patient becomes infected after birth. It is also known, though it is hard to convince the public, that this disease is curable when discovered early and the proper treatment instituted. The finding of the early case and the proper handling of it after it has been discovered should be a field wide enough for one interested in the practice of medicine to find something that would appeal to him. Too many see nothing interesting about it and try to shun it whenever possible. The physician doing sanatorium work is often asked the question by visiting physicians, "How can you do this work? Don't you find it uninteresting and tiresome?" I admit that the work is discouraging when one sees the advanced condition of many patients before anything definite has been done to give them a chance for recovery, but to one who understands the disease and takes the proper interest in the work it will be far from uninteresting. No doubt he who looks upon the disease as uninteresting considers it a hopeless condition in which there is nothing to do but stand round and wait for the patient to die and at the same time administer a little or much cough medicine to help make the last days more comfortable.

When the old ideas regarding the disease have disappeared and the importance of an early diagnosis and what can be accomplished by proper treatment is recognized, it should prove interesting, not alone to the physician doing sanatorium work, but to every one practicing medicine.

The physician will have to realize the importance of an early diagnosis and what can be accomplished when such diagnosis is made. The public is waking up to the fact that the disease is curable in the early stages, and they are going to demand in the future an early diagnosis in order that the chances for recovery may be greater. They are not going

*Read before the Southwestern Minnesota Medical Society at its fourth annual meeting, Windom, Minn., May 13, 1920.

to be satisfied to wait until they have reached a hopeless stage before being told what is the cause of their illness. If instead of looking upon tuberculosis as an incurable disease, the importance of an early diagnosis is realized and the proper method of treatment instituted, the picture takes a different aspect. To diagnose the disease early is by no means easy in every case; in fact, its symptoms and physical signs are so varied and obscure that it is often most difficult. The old picture of emaciation, night sweats, bad cough and high fever should be turned to the wall and earlier and more obscure symptoms studied if an early diagnosis is expected. It requires patience and careful study to make a diagnosis when the disease is in its incipency. There is probably no condition that presents a more varied array of symptoms than incipient tuberculosis. These symptoms which are obscure and misleading are often present before physical signs in the lungs can be recognized, and when one discovers symptoms which point to no definite disease, it is well to keep tuberculosis in mind, for it is often lurking in the early stages.

Don't get the idea I am one who thinks everything is tuberculosis, for I am not. What I want to impress upon you is the importance of an early diagnosis and the patience and careful study often needed in making it. Mistakes are made both in omission and commission because of lack of effort and painstaking study. Don't think that because one member of the family has tuberculosis, every ailment developing in the family should be so diagnosed, and on the other hand don't feel that because one does not have a family history of tuberculosis it cannot develop. Those having the disease with a negative family history often offer a more unfavorable prognosis than those coming from a tubercular family. A number of patients have been referred to sanatoria for treatment when they did not have the disease, because some member of the family had died of it. One case coming under my care recently was that of a child with advanced diabetes, the condition being diagnosed tuberculosis because the mother died of this disease. Another was a patient suffering from lethargic encephalitis diagnosed tuberculous meningitis, the diagnosis being based largely on the fact that a sister of the patient was then undergoing treatment in a sanatorium for tuberculosis. There are many similar instances that might be mentioned, but these will show that too often a diagnosis is made as a result of an idea rather than from close and careful study. Taking the diagnosis of the disease alone into consideration, it should prove interesting to every general practitioner, for he is constantly coming in contact with it, and when he gives the patient what is deserved in the way of diagnosis, being careful not to fail both to make a diagnosis if the disease is present or call it tuberculosis on a superficial study when it is not present. I am sure he will not find it the uninteresting disease it is too often considered. Every physician prides himself on results in treatment; there is no disease in which the results obtained depend so much on an early diagnosis as in tuberculosis. The diagnosis is by no means easy in every case, and often may require that careful examination be made and the clinical symptoms closely studied be-

fore one can either rule out or confirm the presence of active disease. When tuberculosis is really present and a diagnosis of such has been made, the physician has by no means completed his work of diagnosis in many cases. The fact that he has tuberculosis does not rule out the presence of other diseases, and one does the patient an injustice when he attributes all the symptoms to tuberculosis. Often there are other conditions present more serious than tuberculosis, and every effort should be made to discover them. The patient's chances for recovery depend greatly upon how early they are discovered and how successfully they are handled. The associated conditions may be both tuberculous and non-tuberculous. Among the more common tuberculous complications are pleurisy, laryngitis, adenitis, fistula, meningitis, tuberculosis of the bones, joints, intestines, peritoneum, and other less common complications. Among the non-tuberculous probably the most common is syphilis, and when this is discovered and properly treated it greatly increases the patient's chance for recovery. Other conditions are diseases of heart, kidneys, nervous system, digestive system, and many other less common conditions that should be looked for and discovered as early as possible when present. The proper handling of the complications is of the utmost importance. Active tuberculosis is often due to these associated conditions which reduce the patient's general resistance so that the disease has a chance to become active. In handling a number of patients with tuberculosis, one has an opportunity to come in contact with a sufficiently varied array of diseases to make it interesting. When one is handling patients in a sanatorium, he has far more to do than simply treat the cases as though they were all suffering from uncomplicated tuberculosis. It is the early discovery of the complications and their proper treatment that offers the best chance to the patients for recovery rather than the treatment of tuberculosis alone.

When the diagnosis of tuberculosis has been made and the general condition of the patient carefully studied, the next thing is what is to be done with the patient to offer him the best chance for recovery. This is by no means the least of the physician's responsibilities. Many prefer not to tell the patient his condition, even after a diagnosis has been made, and let them down easy by informing them they have a slight bronchitis which will clear up quickly, when as a matter of fact they know it will not. Such a method cannot be condemned too strongly, and when a patient is found to have the disease he should be told at once, not only for his own good, but for the good of those with whom he comes in contact. It is not only necessary to tell him his exact condition as nearly as possible, but to impress upon him the importance of doing what he should to recover, and at the same time protect others. When being advised what is best, the patient will often ask: "Doctor, don't you think I can stay at home and get well?" It is here that the physician will often acquiesce to the patient's wishes with the result that he remains at home, thus endangering the other members of the family, some of whom will become infected, especially if there are young children in the home.

Even at the present time the old idea prevails

that the West is the only place in which one suffering from tuberculosis can recover, and the patient is advised to go there regardless of conditions. While some patients will do better in the West than in other places, many things should be considered, such as financial condition, whether the patient would become homesick, or whether the journey would do more harm than change of climate could possibly counterbalance. There is no climate that will suit every case, and there are other things that are of far more importance to the average case than climate alone. These conditions should be considered, and if too great a sacrifice must be made for climate it is better to do without the climate. Patients suffering from tuberculosis recover in any climate, but few will recover anywhere when they are discontented and the financial condition is such they cannot get the proper treatment. All these things should be carefully weighed before advising a patient what to do. The greatest thing is to live the proper life for recovery and learn to take precautions to prevent the spread of the disease. The active case is not dangerous when precautions are taken. There is no safer place for the healthy person than in a sanatorium where such precautions are taken, for there he can protect himself, while in the outside world he cannot, for he does not know when he is coming in contact with a patient in the active stage who is careless.

The use of drugs in the treatment of tuberculosis is of very little value, though occasions arise during treatment in which they may be of service in the relief of certain conditions. About everything in the pharmacopeia has been used, and no specific for the cure for the disease has been found. Fresh air, good food, rest and exercise properly used are of far more value than anything else yet discovered. When a patient is in condition to begin exercise it should be prescribed as carefully as a dose of medicine, for often overexercise causes a reaction which may prove disastrous. Many are those who have filled an untimely grave because of being advised to go to the country to camp and exercise in the fresh air.

These are a few of the many things which should prove of interest, not alone to the specialist handling the tuberculous, but to the general practitioner. When the disease is carefully studied both previous to a diagnosis and during treatment for the purpose of rendering the greatest good to the patient in particular and humanity in general, there should be much that would prove of interest to the physician from both a scientific and a sociological standpoint. In all its aspects it must be studied broadly, and every effort should be made not only for its discovery and treatment, but for its prevention as well, in order that this and future generations may be protected.

Incomplete Millard-Gubler Syndrome.—Ausset and Brassard report a case of this syndrome in a girl of 10 years. The course was subacute, there was no paralysis of the external motor oculi and the case ended in recovery after the establishment of a fixation abscess. The syndrome probably was a manifestation of encephalitis lethargica, despite the absence of ophthalmoplegia. In discussion Professor Comby regarded the case as one of subacute encephalitis of unusual location. He took occasion to deplore the practice of setting up curative abscesses.—*La Presse Médicale*.

AUTOTRANSFUSION FOR HEMORRHAGE.*

BY G. R. LOVE, B.S.

CHICAGO.

THE therapeutic value of blood transfusion to stop hemorrhage was discovered by the pioneers of blood transfusion, who observed that when the transfusion was performed for hemorrhagic anemia the hemorrhage itself was often checked. The clinical data to this effect are common. However, there is a considerable paucity of experimental data. Ottenburg¹ reports that in a case of hemophilia the coagulation time was reduced temporarily from one hour and twenty minutes to seventeen minutes by a 150 c.c. citrate transfusion. Bernheim² checked the hemorrhage of a duodenal ulcer with a 500 c.c. citrate transfusion where six doses of horse serum had failed.

The citrate for some time received the credit as the therapeutic agent in transfusion for hemorrhage. However, since the transfusion of whole blood, as by Lindemann's³ method, has the same effect in stopping hemorrhage, it is obvious that a therapeutic agent comes from the transfused blood itself. Although, as Bernheim⁴ has stated, this phenomenon has not been definitely explained, the fact that the blood is brought in contact with a foreign surface must be considered as a probable factor. It is well known that contact with a foreign surface hastens the coagulation time of normal blood, and we may assume that in such instances some substance concerned in normal coagulation is either activated or increased in concentration. According to the present terminology this substance would probably correspond to thrombokinase. Thus in a transfusion the recipient receives blood which is in a pre-coagulative state and therefore it will coagulate easier when exposed the second time, that is, at the point of hemorrhage. It is obvious that in hemophilia the deficient substances are supplied by the donor.

Lewishon⁵ observed that the coagulation time could be reduced even by autotransfusion, and states that a 300 c.c. autotransfusion on a dog reduced the normal coagulation time of five minutes to ten seconds. Although the author's results do not approach Lewishon's data, they point to the same end, and the difference may possibly be explained by the technique and methods used in testing the coagulation time. It has been our experience in this laboratory that blood which in ten seconds will form a visible coagulum was originally in the last stages of coagulation. In view of these facts autotransfusion was studied more extensively with an improved method of testing the coagulation time.

Technique of Autotransfusion. Any of the ordinary methods of transfusion of whole or citrated blood may be used for autotransfusion; however, the method which we have found the easiest and most applicable is as follows: A tourniquet is applied above the field and the vein is punctured with a short 15-18 gauge needle in the usual manner. The blood is aspirated into a 10-20 c.c. Luer syringe to the capacity of the syringe. The tourniquet is released and without disconnecting the syringe the blood is injected back again. Each

*Contribution from the Department of Chemistry of the Hahnemann Medical College of Chicago.

single aspiration-injection process should be performed in one to two minutes and they are continued until the total amount of blood handled is equivalent to or greater than an ordinary transfusion.* One syringe is used continuously for from three to five minutes and then it is rinsed in 5 per cent. sodium citrate or normal salt while the process is continued with a second syringe. About 2-5 c.c. of physiological salt solution should be injected at each change of syringes to insure a clean needle.

The manipulation of the tourniquet depends upon the circulation and its proper use is a matter of judgment on the part of the operator.

Experimental Data.—The following experiments were performed upon dogs under ether anesthesia by tracheotomy. The coagulation time was tested by the capillary tube method described by the author,[†] and by the test tube or Hayem's method.

Protocol, Dog 1, 10 kg. wt., blood withdrawn from femoral artery for testing coagulation time. External jugular used for autotransfusion. Temperature of room 20° C.

3:30 P. M.—Dog anesthetized.

3:45 P. M.—Coagulation time, capillary tube method, 7' 15".

Coagulation time, test tube method, 12'.

Aspirated and injected 100 c.c. blood with a 10 c.c. syringe in 12 minutes.

4:15 P. M.—Coagulation time, capillary tube method, 6' 35".

Coagulation time, test tube method, 15'.

Aspirated and injected 100 c.c. again in 15 minutes.

4:45 P. M.—Coagulation time, capillary tube method, 4' 45".

Coagulation time, test tube method, 9'.

Protocol, Dog 2, 8 kg. wt., blood withdrawn from femoral artery for testing the coagulation time. Autotransfusion in external jugular. Temperature 24° C.

2:00 P. M.—Dog anesthetized.

2:30 P. M.—Coagulation time, capillary tube method, 5' 45".

Coagulation time, test tube method, 16'.

Aspirated and injected 100 c.c. in 10 c.c. syringe in 15 minutes.

3:30 P. M.—Coagulation time, capillary tube method, 4' 55".

Coagulation time, test tube method, 15'.

Aspirated and injected 100 c.c. in 10 c.c. syringe in 12 minutes.

4:30 P. M.—Coagulation time, capillary tube method, 4' 10".

Coagulation time, test tube method, 10'.

Aspirated and injected 100 c.c. in 10 c.c. syringe in 14 minutes.

5:00 P. M.—Coagulation time, capillary tube method, 4' 10".

Coagulation time, test tube method, 8'.

Protocol, Dog 3, 12 kg. wt., blood withdrawn from the femoral artery for testing the coagulation time. Autotransfusion by Lewisohn's citrate method from femoral artery to femoral vein. Temperature 20° C.

3:15 P. M.—Dog anesthetized.

3:40 P. M.—Coagulation time, capillary tube method, 7' 50".

Coagulation time, test tube method, 18'.

300 c.c. blood withdrawn to 0.25 per cent. citrate (final concentration).

4:00 P. M.—Blood injected.

4:05 P. M.—Coagulation time, capillary tube method, 6' 35".

Coagulation time, test tube method, 15'.

4:40 P. M.—Coagulation time, capillary tube method, 4' 40".

Coagulation time, test tube method, 10'.

*The use of the word *autotransfusion* in describing this process is obviously a misnomer, although the slight difference in technique does not warrant a new nomenclature.

In the foregoing experiments the capillary tube and the test tube methods were employed because they represent two extremes. In the capillary tubes the area of contact of the blood with a foreign surface is very great, while in the paraffined test tube it is minimal. Consequently the percentage reduction of the coagulation time is greater in the test tubes than in the capillary tubes after the autotransfusion. However the test tube method is by no means accurate and the foregoing tests are the averages of triplicate tests.

Five other similar experiments were performed with the same general results, but there was some deviation in the duplicates, which should be expected in experiments with so many factors. It must not be overlooked that in the above experiments the actual hemorrhage in each instance would lessen the coagulation time. Several attempts were made to determine the actual bleeding time before and after autotransfusion by irrigated foot pads, lacerated wounds, and incised wounds. This type of experimentation was finally abandoned because no constant normal could be obtained for comparison. It should be pointed out in this connection that many factors, such as blood pressure, contractibility of the vessels, rigidity and tension of the surrounding tissues, size of the vessels, amount of laceration, etc., enter into the determination of the actual bleeding time. From this it may readily be seen that the bleeding time and the coagulation time are not related in any simple manner. However, it can be stated that in our experiments on bleeding time, wounds which would ordinarily have bled very severely were quite easily controlled after autotransfusion.

Since all of our experiments were upon normal blood the adaptability of autotransfusion for hemorrhage in cases where the coagulation time of the blood is abnormal is yet undetermined.

2511 COTTAGE GROVE AVE.

A Male Pseudohermaphrodite With Well Developed Vagina.—Recently a case of this sort was reported by Schwartz in a Paris clinic and cited in the *MEDICAL RECORD*. A similar case has been seen in the clinic of Rochard and is reported by Constantini. The subject was apparently a woman of thirty-four with left inguinal hernia which was to be operated on. The sex was apparently feminine without reservation, but in the course of operation a testicle with epididymis and vas was encountered in the hernial sac. The author refused to remove such an organ without a better indication, for it definitely fixed the sex of the individual. The latter was married to a man but had never menstruated. All of the female secondary sexual characters were present. The external genitals and anus were distinctively feminine and the vagina was ample for copulation, but uterus and tubes were absent. Sexual relations with the husband were found to be normal and the couple were not told of the mistake in sex. The author mentions the cases of Schwartz and Guillaume, which were of the same type as his own.—*Le Bulletin Medical*.

A NEW PROCEDURE FOR MEDICAL SOCIETY MEETINGS.

THE Association for Neurological Research which held its first meeting in this city last week has successfully inaugurated a new method of conducting medical meetings.

From the beginning of formal medical organizations, the procedure has been about the same: a paper is read or a case is shown, a discussion is invited, then another paper and more discussion. Or a symposium is prepared, with several important persons contributing to the different phases of a chosen topic. This procedure is meritorious and no doubt will continue to be used.

But the new method of the Research Association has certain special merits which obtained for it, prompt and quite enthusiastic approval: It may be called the commission or committee method and is really very much like that of a court procedure or more especially like that of a committee composed mainly of experts who set out to learn all there is to learn about a given subject.

In the present instance the object to be studied was "epidemic (lethargic) encephalitis." In the early part of last year (1920) various phases of this topic were assigned to those men thought best equipped to investigate and report upon them. A so-called commission of seven was appointed; and the papers to be presented were, just before the meeting, sent to the various members of the commission for examination. At the time of the meeting the author was called to the stand and he there presented his views in full or in abstract. He was then questioned and cross-examined by the commission, and by other members who sent in written questions. The papers were thus not so much discussed as constructively criticised and all possible points of view were brought out. The writers of the papers cooperated with the procedure; the interchange of views was very intimate and human, and practically very interesting. There was none of the casual or tiresome discussions nor airing of personal convictions and every moment of the two days' session was effectively used. As a result over twenty contributions, representing perhaps a year or more of study, were read or adequately presented.

A report containing abstracts of the papers and of the questionnaire will be published. Topics for December 1921 and 1922 have been assigned.

As the Association was represented by men of national reputation from the eastern and middle western States, it is likely that the commission plan of medical meeting will be widely discussed and adopted for at least certain kinds of scientific work. The old way of paper and discussion is not adapted to bring out effectively the best that is in the reader or the most that is in the subject.

THE CLINICAL ASPECTS OF LATE HEPATIC ABSCESSES, THE RESULT OF TROPICAL DYSENTERY.

DURING the long lapse of time between the initial attack of dysentery contracted in the tropics and the development of abscess of the liver no local or general reaction may occur. In other instances this long period of remission is marked by indefinite intermittent paroxysms of which signs vary from one case to another. These paroxysmal occurrences consist of gastrointestinal disturbances, attacks of fever without chill and uninfluenced by quinine, lasting for several days without interfering with the general health, which usually is good; intermittent and deep-seated pains in the epigastric region without any localization and giving the sensation of constriction.

Later on when the liver becomes irritable from the developing abscess, the symptomatology becomes more precise. There are emaciation, adynamia, and, in some cases, headache and insomnia. A more or less localized pain in the right hypochondrium will be complained of; it is intermittent and increased by palpation; superficial at first, it becomes deep-seated later on. In other cases the pain may radiate to the right shoulder, in about 17 per cent., according to Rouis. When the right pleura reacts to the process in the liver there are cough and dyspnea. There may be some evening rise of temperature with sweating, but no chill. The complexion is pale but icteric in only about one-sixth of the cases, according to Rouis. The sclerotics are waxy white, a characteristic symptom referred to by Sachs. There is irritability of the nervous system.

Inspection reveals a tumefaction in the right hypochondrium resulting from the hepatic hypertrophy combined with an outward spreading of the last ribs. Palpation reveals an enlarged liver, painful over a limited area of the surface of the organ. In the proximity of the abscess there is a hard, smooth, and even tumefaction, painful on deep pressure. Spreading of the right intercostal spaces may be observed. Perihepatic friction sounds, due either to edema of the liver (Hassler, Boisson) or to perihepatitis (Bertrand) are not constant. Percussion shows an increase of the liver dulness above, while below it extends several fingers' breadths downward from the costal border, and behind it extends to the tip of the

scapula and the tenth rib. The other viscera offer no change; the spleen is not enlarged, the heart and pulse are normal. In some cases there may be evidence of chronic pulmonary congestion. The urine is free from sugar and albumin, likewise urobilin, while the amount of urea is normal (Parker, Lecorché, Cayley).

Hematological examination shows a decrease of the red blood corpuscles (Léger) and hyperleucocytosis and polynucleosis (Boinet, Bertrand, Sardat, and Morel) of 73 per cent. Marchoux supposes that this polynucleosis indicates a bacterial infection of the abscess. The eosinophiles represent 2 per cent. of the count.

Roentgen ray examination in the case of large abscesses on the convex aspect of the liver will reveal the costodiaphragmatic sinus, the situation of the pus pocket and in some cases of abscess on the superior aspect of the organ, the rising up and immobilization of the right half of the diaphragm (Béclac).

A rectoscopic examination reveals apparently healed intestinal ulcerations in patients formerly afflicted with tropical dysentery and this datum may be useful in those instances where a former attack of tropical dysentery is wanting in the case history.

Puncture of the liver as a diagnostic measure is needless and is to be condemned.

PRESUMPTION OF TUBERCULOSIS FROM EXTERNAL STIGMATA.

QUEYRAT, apparently turning his back for the nonce on serodiagnostic and bacteriological tests, interests himself in the old-fashioned methods of diagnosis from deduction (*Le Progrès Médical*, November 6, 1920, xlviii, 45). The author enumerates in rapid succession the slenderness of the long bones, the defective development of the musculature and especially that of the thorax, where there is actually atrophy of some of the muscles which appears to result from the presence of a focus of disease in the apex of the affected side. However, in the case of these petty signs it is not always possible to distinguish between the candidate for phthisis and the early victim. Atrophy of the trapezius, great pectoral, etc., is one of the presumptions that a focus is already present. Percussion myoidema of phthisiologists is an induced phenomenon in the same muscles. But it should be borne in mind that myoidema is common to cachexias and is without specific significance. Pectoral myoidema (or myedema) was extremely common in an epidemic of cholera in 1835. It is common also in cancerous cachexia. Winglike scapulæ is due to atrophy of the serratus magnus and is seen in candidates and even in those who do not seem predisposed to the disease. Tall and slender subjects of the so-called "poplar" type are to be classed as candidates. The author mentions in passing the facies amabilis of old clinicians—with its long oval, its mobility, its thick eyebrows, long lashes, and bluish sclerotics. The eyes are

especially languishing and beautiful. Chlorotuberculosis is a special form, with various hypoplasias, including those of the genitals, which is said to be readily curable. Of other petty signs the author enumerates thickish skin, lively blush on the cheeks, thick lips, wide nose, chilblains, fissures between the cheeks and lobule of the ears, deceptive appearance in plump subjects because of the good nutrition, high color, and clear eyes.

Hippocrates, who presumably lived among a population containing a large percentage of dark-complexioned peoples, laid emphasis on red hair, clear skin, and blue eyes as predisposing to phthisis. But it is not so much the exclusively rufous subject who seems to invite the disease, for brunettes of the "erythristic" type suffer equally with the blondes and rufous. That is, in tuberculous subjects we often find a hybrid between brunette and red, as when black head hair is associated with red beard or pubic hair. Hirsute subjects, when this trait is not associated with the cave man proportions, are very suggestive of phthisis. This is shown in an old Latin maxim—"a hairy man is either strong or consumptive." Rather suspicious in girls are plump mammae with general lack of adipose. Smallpox scars in a subject suggest the old dictum that the victim of variola very often dies of or with tuberculosis, as shown by autopsy finds. Scars of old scrofula, scar keloid, and perhaps spontaneous keloid are all suggestive of tuberculosis, past or future. The author concludes with a long parade of the so-called paratuberculous dermatoses which have gradually increased in numbers to such an extent that they are often the only evidence which points to the disease.

THE DIAGNOSIS AND PROGNOSIS OF MUSHROOM POISONING.

THE accidents ensuing from the ingestion of poisonous mushrooms in some instances might at first sight lead to the diagnosis of a mere indigestion; in others the clinical picture is that of cholera or typhoid fever, occasionally delirium tremens, or even an acute suprarrenalitis. If the patient be questioned closely, however, one will learn that he has partaken of a dish of mushrooms. Besides these anamnestic data and the clinical picture offered, research for débris of these cryptograms and their spores in the vomitus and liquid stools should be made, and if a blood examination can be done the diagnosis will invariably be an easy matter. Should the clinical picture presented by the patient appear to be somewhat abnormal and therefore to cause hesitation, the physician will usually have the opportunity of finding a more or less typical one in one or several of the other members of the family or in friends, because mushroom poisoning generally assumes the character of a *collective* outbreak. It should also be recalled that each syndrome need not of necessity occur in a pure type, because the same plate of mushrooms may contain assorted

cryptograms, hence the possible combination of the resinoid, muscarine, and phalline clinical phenomena.

The prognosis *quoad vitam* is excellent in respect to the so-called suspicious mushrooms. In general muscarine poisoning is serious but not fatal. Death has been met with in only a few cases, in children or elderly people, and in adult subjects with cardiac, renal, or hepatic lesions. The rapid onset of the accidents, the suddenness of the vomiting and diarrhea—which together eliminate the *causa delictus*, the promptness of medical aid, and finally the nature of the poison, are the factors of the relative benignity in the circumstances.

The question takes on quite another aspect in poisoning from phalline. The tardy development of the accidents, vomiting, diarrhea, anuria, and pulmonary, gastric, and intestinal hemorrhages darken the prognosis. Stupor, somnolence and absence of vomiting and watery stools is of very bad augury. The mortality is about 80 per cent. in these cases. The prognosis is rather more assuring when the intoxication has not been too massive. In other words, when one is dealing with a vigorous adult in fine health, also when there has been a mixture of phalloid amanita with other poisonous mushrooms which produce vomiting, and lastly, when the physician is summoned without too great a delay. Taking all things into consideration the prognosis is generally extremely dark, and it is of utmost importance, regardless of our early and active treatment, to warn the *entourage* that the outcome may be fatal. This precaution having been taken, it remains with the attending physician to do the best he can, the therapeutics of this dire toxic being, to say the least, precarious.

POST-SERIC TETANUS.

THAT tetanus may develop despite preventive serum inoculations is well recognized and may mean defective technic or false conceptions of the actual conditions. The injections must have been made as early as possible, and it must be remembered that the protection may run out if the injections are not renewed periodically. A thesis on the subject of the University of Lyons (1919) by Vitu is briefly reviewed in the *Journal de médecine et de chirurgie pratiques* for July 25, 1920, xci, 14. The question is the direct outcome of the war and may not apply strictly to industrial and accidental tetanus. It is conceded that as soon as a subject has received a wound he should receive an injection of 10 c.c. of serum and that this should be repeated on the eighth day. If this *modus vivendo* fails to protect, it will usually be due to latent microbism and there should be no surgical intervention in these subjects—in connection with the original wound area at least—without a special additional injection. One should in addition never forget that the serum used may not come up to the desired standard and only the best and freshest supply available should be used with all aseptic precautions. There are two types of post-seric tetanus, precocious and late. Characteristic of post-seric tetanus is its mild

course, and a severe and fatal early case following injection may be regarded as *prima facie* evidence that the serum has been inert; but no cases of this sort are known to have occurred. Precocious seric tetanus is attenuated and localized, but in the late form we do not see this attenuation and the protection seems to have expired; so that early trismus, hyperthermia, sweats, etc., develop as in cases in which no preventive injections have been used.

MONTÉGIA'S DISLOCATION.

A CASE of this rare accident was reported by Clap to the Paris Anatomical Society (*Bulletins et mémoires de la Société anatomique*, 1920, xvii, 7). The patient was knocked down by an automobile and, though conscious, was unable to rise, and was taken to the Saint-Antoine Hospital, where he was seen by Professor Lejars. In addition to numerous minor injuries which need not be detailed his right hip was found to be immobilized in the position of almost complete extension with marked external rotation. There was a shortening of two finger breadths and a slight prominence in the external portion of the groin, while in the rear there was a larger prominence. The fold between the ischium and the trochanter was shortened. In all the localities mentioned there was tenderness on pressure. The radiogram showed a dislocation of the hip with the head of the femur in the shadow of the trochanter and almost completely out of contact with the acetabulum. The patient was placed under chloroform and the luxation readily reduced by traction, flexion to 45 degrees, and internal rotation. The chief interest of this dislocation is its close resemblance to fracture of the neck of the femur. Technically it is only a variation of the ordinary iliac dislocation in which the head of the femur is directed in front instead of behind. The position of the lesser trochanter in the radiogram showed that the head was situated forward.

News of the Week.

Conference on Venereal Disease.—The All-America Conference on Venereal Diseases and Social Hygiene, held in Washington during the week of Dec. 20, 1920, was the first of a series of conferences planned by the International Health Conference in Cannes, France, in April, 1919. The conference was presided over by Dr. William H. Welch and attended by representatives of the allied nations that fought in the war. The second conference will be held at Copenhagen, Denmark, in May, 1921, and will be attended by delegates from all the Scandinavian countries, and from Holland and Great Britain. Later in 1921, conferences will be held at Paris and at London. The conference in Washington was conducted along lines somewhat different from those usually adopted for medical conventions in that there were fewer set papers and the delegates were divided into committees each of which considered different problems. The results of such deliberations were then submitted to the general conference. The manner in which some of the questions have been answered is illustrated by the following resolutions adopted by the Conference: In reply to a question as to the establish-

ment of immunity to gonorrhea and syphilis, the Committee presented the following resolutions: "With reference to gonorrhea, there is no evidence of the establishment of any immunity to the disease beyond that of a more or less temporary immunity in the case of existing, individual infections. Such a temporary relative immunity may be lost either as the result of disturbed relations between the infecting organism and the host through the introduction of a new gonorrheal infection. With reference to syphilis, there is no evidence of an absolute and permanent immunity to syphilis unless it be that due to an existent infection. There is evidence to show that infection may exist without obvious manifestation of the disease. The immunity ensuing in such an infection may extend even to the degree of a commensal or symbiotic adaptation." With respect to the Wassermann reaction, it was resolved that: "The blood Wassermann should not be used as a sole guide to the duration of syphilitic infection. The blood Wasserman reaction should not be used as the sole evidence of the effectiveness of a particular drug or method of treatment. The blood Wassermann reaction should not be used as the sole evidence of 'cure' no matter how many times repeated." Another resolution states that: "The complement fixation test has not yet been shown to be of value in the diagnosis of doubtful cases of gonorrhea. It is possible, however, that the precipitin test recently reported by Meader and Robinson may be of great value." Exhibits and demonstrations were features of the work of the Congress. Among the four hundred delegates in attendance were representatives from Argentina, Brazil, Chile, Ecuador, Cuba, Honduras, Mexico, Paraguay, Porto Rico, Canada, Czecho-Slovakia, and England.

Prohibition Gets Credit for Decrease in Insanity.

—According to a report submitted by Dr. Horatio M. Pollock, chief statistician of the New York State Hospital Commission, there has been, since the advent of prohibition, a considerable decrease in the number of persons committed to the State hospitals for the insane. The data gathered by Dr. Pollock shows that a considerable percentage of the cases of insanity in the State was caused by the excessive use of alcohol. In 1909, for instance, 10.1 per cent. of the persons committed had become insane due to excessive use of alcohol. During the year 1920, the percentage of insanity cases caused by alcohol was only 1.9. In this connection the report mentions that the increase in drug addiction predicted by some as the result of prohibition has not made itself felt in statistics dealing with insanity. Narcotic drugs are lesser factors in this respect today than ever before in the history of the State. Among those suffering from insanity induced by alcoholism, it is found that the men far outnumber the women. This situation is reversed when it comes to drug addiction. Here the women lead the men at a ratio of about four to three. During the past twelve years there have been only 234 first admissions of known cases of insanity due to narcotic drugs, while for the same period 15,625 first admissions are attributed to alcoholic excesses.

Spain Restricts Doctors.—A dispatch from Madrid announces that a royal decree has been issued giving foreigners the right to practise medicine in

Spain in the event their countries give reciprocal treatment to Spanish physicians. This decree follows a recent outcry from Spanish members of the profession against an influx of foreign physicians who were permitted to practise without passing the Spanish medical examinations.

Smallpox in New Jersey Town.—According to the New Jersey State Department of Health, there are at least eight cases of smallpox in Keyport. The State Department of Health has warned other communities in that district against welcoming visitors from Keyport. As the disease assumes a mild form it is suspected that a number of unreported cases exist.

New Hospital Ship.—The largest and most completely equipped hospital ship in the world was placed in commission as a United States Naval auxiliary at the Philadelphia Navy Yard, on Dec. 28. The vessel is called the *Relief* and is the first vessel constructed by any government exclusively for naval high seas operation, as an auxiliary unit of the battle fleets. In addition to a bed capacity for 500 patients the new hospital ship has an "out-patient" department similar to the dispensary and clinical service of a city hospital. One of the novel features of the equipment is a machine for making fresh milk and cream from ingredients carried in concentrated form. It is pointed out that this device is of inestimable value in caring for the sick in the tropics where it is impossible to obtain fresh milk. The ship is equal in capacity to a hospital serving a population of 30,000.

Promise of New Medical School for Columbia University.—Speaking at the annual luncheon of the Columbia Club recently, W. Barclay Parsons, Chairman of the Board of Trustees of Columbia University, announced that plans had been formed for raising \$10,000,000 to be used in erecting and endowing a new medical school which would supplement the present College of Physicians and Surgeons. Of the \$10,000,000 fund \$5,000,000 is to be used as an endowment. Mr. Parsons expressed himself as confident that during the next year substantial progress will be made toward the realization of this project.

The Health of New York During 1920.—The mortality statistics of New York City for the first eleven months of 1920 show that there have been 67,693 deaths reported during that period, as compared with 68,728 deaths during the corresponding period of 1919. The death rate from Jan. 1 to Dec. 1, 1920, was 12.01 per 1000 of the population, as compared with a rate of 12.51 in the first eleven months of 1919. A noteworthy feature of the mortality during the year has been the increase in the death rate among children and among the aged, as compared with the mortality of the year 1919. Among infants under one year of age there were 697 more deaths, which is partly explained by the increased number of births, there being 2479 more births during 1920 than during 1919. Of every 1000 infants born during the past year 86 died, as compared with 83 for the year 1919. There were 1598 more deaths of children under five years of age during the year 1920 than during 1919. This increased mortality among children was due to the epidemics of measles and whooping cough which prevailed from January to June of 1920. There was

also an increase of 220 deaths from gastrointestinal diseases during the year. The report shows a decrease of 1340 deaths from influenza; 686 from diseases of the respiratory organs, and 1317 deaths from all forms of tuberculosis, as compared with 1919. During the year there was an increase of 851 deaths among those 65 years of age and over from the so-called degenerative diseases, such as organic heart and kidney disease, cerebral apoplexy and arteriosclerosis. The mortality from homicides increased from 279, in 1919, to 323, in 1920; the death rate from this cause, however, remained practically the same for the two years under consideration.

British Death Rate Falls.—The annual report for 1919 of the Registrar General for England and Wales shows that the probable loss of births attributable to the war may be somewhere over half a million, or very similar to that of deaths on active service. By way of compensation the report shows the lowest death rate yet recorded for measles and whooping cough during 1919, and that the former low death rate from diarrheal diseases has been bettered. The excess of infant deaths in London over the average for the country which was noted as an exceptional feature of the reports of 1917 and 1918 figures has disappeared.

French Birth Rate Increases.—According to the *Journal Officiel*, the year 1919 was characterized by a great increase in marriages, a slight increase in births, and a marked falling off in deaths. The number of marriages for 1918 was 177,822; for 1919, 458,363. The number of births reported for the year 1918 was 399,041, while that for 1919 was 413,379. There were during the year 1919, 615,694 deaths as against 788,616 for 1918. The report states that to these may be added the figures from Alsace-Lorraine, where the marriages numbered 23,977; births, 28,192, and deaths, 25,556.

Smallpox in Chicago.—One hundred cases of smallpox have been reported up to Dec. 31 from the town of East Chicago, nine cases from Gary, and seven have been found in the East Side district in South Chicago. It is said that the disease got its start through the wrong diagnosis of a case of smallpox by a physician, who mistook the disease for chickenpox and told the patient there was no need for his remaining at home. Quarantine in East Chicago is being enforced by squads of special policemen.

Hiccough Epidemic Appears in New York.—According to the Department of Health, the number of cases of hiccoughs reported throughout the city shows that the complaint has reached the stage of a general epidemic. More than 150 of the inmates of the Tombs Prison have been affected by hiccoughs.

Red Cross Program for 1921.—The New York County of the American Red Cross announces that it intends to devote its energy to the development of several kinds of health work in Manhattan during the coming year. Child health stations are to be conducted in various parts of the city where undernourished school children will receive expert care. In cooperation with the City Health Department the organization is undertaking experimental work at Public School 43, where several nutrition classes will be conducted and where a dental clinic will be

established and dental hygiene taught. A health information bureau is to be established at Greenwich House, 27 Barrow Street, where lectures will be provided for mothers' clubs, shops, settlements, and other organizations wishing such instruction. During the past eight months 34,650 persons have attended lectures given by the bureau. A diet kitchen will be conducted at 24 Fifth Avenue, where wholesome home cooked food for invalids may be obtained at cost. It is hoped eventually to transport this food to the homes of the sick. The New York Chapter will continue to give help to ex-service men.

Digitalis Tests Not Cruel to Cats.—An advertisement by E. R. Squibb and Sons for cats, for the purpose of conforming with the government regulation requiring that digitalis must be tested on animals before it is sold, resulted in calling out in force the New York branch of the American Antivivisection Society, which is greatly concerned lest the Squibb cats are not being treated humanely. In order to settle the question the New York Society for the Prevention of Cruelty to Animals has made an investigation of the method employed by the Squibb Company, and reports that the cats are humanely chloroformed and then used to determine the strength of digitalis, and that no cruelty is exercised toward the animals.

Hospitals and Institutions Asked to Make Complement Fixation Tests.—The New York State Department of Health has asked that all hospitals make a complement fixation test of the blood as part of their routine examination of patients. A survey of hospitals, both state and private, has been made, and where this practice has not already been instituted the authorities have been asked to adopt it. In order that some institutions, such as orphanages, tuberculosis and state hospitals, may better carry out this work in the future the Department has offered to assist them in taking the specimens from their present resident population. Thirty-four institutions have accepted and received such assistance prior to Sept. 1, 1920, and eighteen others have asked for it. Less than 2 per cent. of the persons thus tested were found to have a definitely positive reaction with both antigens, while more than 40 per cent. showed suggestive reactions with one or the other antigen.

Medical Service in Rural Districts.—The *Monthly Bulletin* of the New York State Health Department reports that during the past year information has been received from 76 rural districts in 36 counties of the State of New York that medical service is either inadequate or not procurable. More than half the informants were residents not serving in any official capacity; public officials and physicians made up the balance. The population of these districts varied from 500 to 6000, the nearest physician being from five to ten miles distant. Forty-seven districts have been supplied, while 29 communities are still in need of medical service.

Relief Unit for Eastern and Central Europe.—A relief unit of twenty American specialists, sanitarians, dentists, and pharmacists, under the direction of Dr. Harry Plotz, medical adviser of the Jewish Joint Distribution Committee, will sail for Europe on Jan. 15. The unit will serve for one year in the war stricken countries of Eastern and Central Europe. The unit will furnish medical

supplies, surgical instruments, etc., to local doctors and hospitals which now lack all supplies. It will also cooperate with the governments in fighting epidemics, principally typhus, conducting educational campaigns, building baths, furnishing soap and fuel, and organizing boards of health in each community so that the work will be continued after the unit leaves Europe. The Joint Distribution Committee has appropriated \$2,000,000 for the unit's work.

Dr. James J. Walsh of New York was recently elected president of the American Catholic Historical Association.

Needs of the American Hospital in Paris.—Subscriptions to the American Hospital in Paris totaled more than 10,000,000 last year toward the 16,000,000 francs required for the construction of a 100 bed addition and the improvement and maintenance of the institution. During the next year the hospital fund officials will concentrate their efforts toward obtaining 4,000,000 necessary for the addition and will apply all donations for that purpose.

Larger Staff for Ellis Island.—Owing to the fact that thousands of immigrants are waiting on ships and on Hoffman Island for examination before being admitted to the country, the Secretary of the Treasury and the Secretary of Labor have been asked to increase the staff of doctors and inspectors at Ellis Island.

The Late Dr. Meltzer.—At a special meeting of the Council for the New York Society for Thoracic Surgery, the following resolutions were adopted upon the death of Dr. Samuel J. Meltzer: *Whereas*, on Nov. 7, 1920, death removed from the roll of this Society our distinguished colleague, Dr. Samuel J. Meltzer, and *Whereas*, during his membership in this young association Dr. Meltzer had been an active worker and an ardent and enthusiastic supporter of the objects which called the Society into being; and *Whereas*, by his formal communications as well as by his illuminating discussions, in fact by his mere presence, he had been a continuous source of inspiration to its members; and *Whereas*, his important discovery of overcoming the dangers of acute operative collapse of the lung by means of his world renowned "intratracheal insufflation" is an epoch-making contribution to thoracic surgery, and *Whereas*, Dr. Meltzer was honored with the office of "First President of the American Association for Thoracic Surgery," the offspring of this Society; therefore, be it *Resolved*, that in the death of our colleague the New York Society for Thoracic Surgery has lost one of its most valued and beloved fellows; and be it further *Resolved*, that these resolutions be spread upon the records of this Society and a copy be forwarded to his bereaved family and to the medical journals. Howard Lilienthal, M.D.; Willy Meyer, M.D.; William H. Luckett, M.D.; Carl Eggers, M.D., Secretary.

Obituary Notes.—Dr. LOUIS JACOBS of New York, a graduate of the College of Physicians and Surgeons, New York, in 1904, died suddenly at his home on Dec. 30, at the age of forty years. Dr. Jacobs was a member of the New York Academy of Medicine, assistant laryngologist to the Montefiore Home and Bedford Sanatorium, laryngologist to the Tuberculosis Clinics, and chief of Ear, Nose and Throat department of Mt. Sinai Dispensary.

Correspondence.

THE RÔLE OF THE MEDICAL PRACTITIONER IN PREVENTING DENTAL CARIES.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Your editorial, "The Cause of Dental Caries" (October 9, 1920) suggests, by its appeal for a solution, a splendid opening to professional fame and fortune for any dissatisfied medical practitioners. If they will take a post-graduate course of two years in dentistry and add D.D.S. to their degree of M.D. they will be a welcome acquisition to our ranks.

As you truly state, ". . . It is undoubtedly an extremely serious problem in all civilized countries, for it is only when primitive people receive the perhaps doubtful blessings of civilization that dental caries is introduced." Dental caries and diseases of the gingiva are as truly scourges of civilization as either tuberculosis or cancer. Fundamentally, caries of teeth and dentoalveolitis are nutritional problems. True pyorrhea alveolaris is a progressive disease from its early gingivitis to maturity. It is almost invariably associated with gastrointestinal disturbances—and personal neglect of mouth hygiene. Blood circulation enters into its clinical consideration, and this feature may be checked up by the size and resiliency of the arteries. These features suggest corrective measures to prevent further congenital transmission. Hepatic insufficiency, which allows an excess of toxins in the gingival tissue, may prove to be the exciting cause of this dental disease. Any excess of glycogen in the mouth tissue cannot be regulated by dental treatments. The interpretation of these problems must be popularized.

The public will be awakened to this truth only by the active and persistent appealing to each individual to practise the laws of self-preservation. The jealous guarding of the economic features of this law was apparent in the recent political election; therefore there is hope that the personal health warning will gain a response.

The dentist and the physician should become live wires on the public platform. The vital interests of our country demand progressive business administration in all departments, and to perpetuate these high principles we must consider the children as our future citizens. Every day practice of body and mouth hygiene must be made pleasantly intelligible.

The Children's Bureau of the Department of Labor, like our public State and local boards of health, is founded on the basis of *prevention*. If the trained minds of the M.D.'s will qualify in the specialty of dentistry, the chances will brighten for a more rapid reduction of the 97 per cent. of dental caries in the teeth of our school children. The 20,000,000 children of our country will have better teeth and their children be immune from dental caries because the combined scientific, organized, nutritional work of the Children's Bureau, public health, dietitians, and mothers, led by the progressive medico-dental profession, will direct body and mouth hygiene from gestation to puberty. The "changes must be rung" until every parent in every hamlet of this rapidly neighboring country will un-

derstand that the vitamines, antiscorbutic, antineuritic elements must be retained in their daily food, by proper cooking and preparation, to insure mouth comfort. Body and mouth hygiene should be taught as being concurrent with the daily elimination of intestinal waste without the aid of drugs.

Your subscriber has observed that athletic children and those children whose food is cooked in vegetable oil rather than in animal fats (with their fatty acids) have better teeth because both of these agents assist nutrition, athletics by intestinal exercise and oil by lubrication.

One of the big problems to solve is the daily cleaning of the teeth and mouth of the school children. The valuable children of the poor must depend upon popular subscription to buy their tooth brushes and dentifrices, for it is a well-known fact that many parents refuse to buy tooth brushes as they need the money for the children's food. It is a well-known fact that the children of the poor are suffering from malnutrition. That means poor teeth. It is a well-known fact that such an object as a "family tooth brush" is a reality among thousands of so-called households. It is a well-known fact that the overworked tooth brush, with the usual laxity of replacement, is one of the principal causes of the diseases of the gums—which include pyorrhea alveolaris. It is a well-known fact that much reinfection is traceable to the abuse of this "product of civilization." It is a well-known fact that the Japanese use their fingers as a medium to massage their gums and teeth and sell us their tooth brushes. It is a well-known fact that cheap tooth brushes are faulty in construction and their loosening bristles cause serious lesions in mouth and throat.

It is an accepted fact among those who have studied mouth hygiene for many years that fruit acids are ideal cleaners of the mouth and teeth. The canned tomato with its sweet acid juice is a splendid stimulant to the mucous membrane and salivary glands of the mouth, and is also a notable antiscorbutic when swallowed. Vinegar, produced from either wine or cider, when well diluted with water is an excellent mouth and teeth cleaner. Tooth pastes and dentifrices are not as popular in Italy, Spain, and France as in the United States, for their native wines are more acceptable as a mouth lavage.

The first action in the mouth of the above by-products of the fruits or of the citric fruit acids stimulates a copious flow of alkaline saliva which holds a full proportion of ptyalin as a medium to convert the starchy foods remaining on or between the teeth into maltose—a form of sugar which readily washes away with the saliva. Clinging particles of meat may annoy one and are summarily removed, but the dangerous starches from bread and soft foods adhere without warning between the teeth and about the gum margins. If not promptly removed the food residue will generate ammonia in the breath which will cause the lime salts of the saliva to be precipitated as calculus irritants to the gingival margins.

We call for medical practitioners to help us. They will gain fame in preventive dentistry and fortune with contentment.

ALBERT WESTLAKE, D.D.S.

500 FIFTH AVENUE.

THE HEMOSTATIC PROPERTIES OF METHYLENE BLUE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—I note an editorial in the *MEDICAL RECORD* of Nov. 27 on Methylene Blue. Its principal virtue as a drug was omitted. It is the best hemostat in the materia medica. It stops bleeding immediately when all other measures fail. In this same article you state that the "pathogenesis of cancer is unknown." This statement is now over six years out of date. I published the cause and pathogenesis of cancer in July, 1914, in the *Medical Council*. I offered an article to the *MEDICAL RECORD*, but it was declined by the editor. The formula "I don't know" has outlived its usefulness in cancer as in many other subjects. It is an overworn excuse for ignorance.

1003 FOREST AVENUE,
KANSAS CITY, MO.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Dec. 10, 1920.

Fighting Tuberculosis.—The International Union Against Tuberculosis which has provisional headquarters in Paris, has now issued to the various national associations for the prevention of tuberculosis the following recommendations, which were unanimously adopted at the recent international conference in Paris: (1) Both doctors and laymen require to be educated in regard to the prevention of tuberculosis. (2) Information should be obtained as to the amount of tuberculous infection, both latent and active, existing in different countries, and especially in relation to the age, sex, and occupation of the population. (3) Accurate figures are required as to the mortality and clinical varieties of tuberculosis in each country. (4) Tuberculosis dispensaries should be established in sufficient numbers, and should be staffed by specially trained doctors, nurses, and health visitors. (5) Adequate provision should be made for the treatment of early cases in sanatoriums and for the isolation of advanced cases. (6) Facilities are required for diagnosing the early signs of infection in infants, for open-air schools and for foster homes in which healthy children born from tuberculous parents may be reared from birth and so preserved from infection. The recommendations quoted above are good. Nothing, however, is said regarding colonies, industrial and agricultural, and village settlements for consumptives. It appears to be the opinion now that sanatorium treatment has failed in so far that it is inadequate. Too much was expected of it. It is said that colonies and village settlements answer the purpose in a satisfactory manner and it certainly is for the good of the community at large that the tuberculous should be segregated as much as possible. An international movement against tuberculosis should have the result of, at any rate, checking the spread of the disease and its progress will be watched with the most intense interest everywhere.

The League of Health.—Reference has been made previously to the League of Health, a body

composed of medical men and civilians to spread the gospel of health throughout the country. Recently, in the public press, the league has published some startling statistics which have been issued by the Governmental Department with regard to the health of the United Kingdom. During 1919 61,715 infants died in the United Kingdom. These did not live for a year; 93,639 children under five years of age, dying during 1917 (no later figures are available), were so mentally and physically defective as to be unable to derive reasonable benefit from the education provided by the rate-payers. In 1918 there were 58,073 deaths from tuberculosis in this country. In 1919 77,616 fresh cases of tuberculosis were reported. The Royal Commission on venereal disease estimates that 10 per cent. of all inhabitants of the large towns in England and Wales have been at some time or other infected with syphilis; 400,000 casualties in the British fighting force from venereal disease would be a moderate computation. All cases of general paralysis and more than 25 per cent. of the blindness in the country are due to this disease. The result of medical examination under the Military Service Acts proved that in this country only one man in three was normally healthy and that one man in every ten was a physical wreck. Four million working weeks are lost in every year through sickness among insured workers in Great Britain. There are more than half a million houses short and among those now occupied are innumerable unsanitary dwellings. Serious and gross overcrowding spell inevitable disease and degeneration of the race. The communication ends with the statement that all these ills are preventable if not curable, if only the people are told how. In the face of such terrible evidence of national evils it is obvious that no patriot can stand outside the great work of disseminating the knowledge which the People's League of Health is undertaking and which alone can mend matters.

Gift to Middlesex Hospital.—The announcement has just been made that the sum of £20,000 has been given by an anonymous donor for the endowment of the University Chair of Physiology at the Middlesex Hospital Medical School. The gift is intended as a mark of appreciation of the importance of study and research in physiology as the very foundation of medical science and practice. It is also interesting to know that Professor Swale Vincent, at one time professor of physiology at the University of Manitoba, now occupies that chair at Middlesex Hospital. It is interesting because Swale Vincent a short time ago gave an address in which he deplored the fact that science, and perhaps medical science in particular, was starved in this country. He pointed out that in America rich men were lavish in their gifts to medical science, but that the wealthy here were chary of giving for this purpose. His remarks seem to have borne fruit, as it is something more than a coincidence that shortly after his speech this gift should have been made for the endowment of the very chair he occupies. It may be mentioned that there are now six professorial chairs in connection with the Middlesex Hospital.

A Nursing Scheme for Manchester.—A meeting

was held in the Manchester Town Hall on November 29 last, attended by about 130 representatives of approved societies, at which a great nursing scheme was initiated and approved. In March last a resolution was passed in favor of the extension of the nursing institution in Manchester "with a view to supplying nurses for the Public Health Office and to meeting any calls from the Insurance Committee and from the Approved Societies for the Nursing of Insured Persons . . . and that grants be made . . . to maintain the additional staff necessary for these purposes." The extension would entitle a doctor attending an insured person to call for a fully qualified nurse to look after the case. The extended organization has now been made, the Manchester Insurance Committee having approved a donation of £1,000 and the Public Health Committee a grant of £500, and the scheme was presented for the approval of the representatives. As it is designed for the benefit of the societies' members, and as the Nursing Association's income must be largely augmented by contributions from the societies, their approval was required. The scheme involves a local contribution of 3d. per insured person, which would bring in about £3,000 a year. This amount would enable the staff of nurses to be adequately increased and properly paid. The draft scheme was passed unanimously, and it was decided that the representatives should recommend to their societies the payment of 3d. per insured person to the association. In this connection it may be pointed out that, while the scheme is an excellent one, the supply of fully qualified and well-trained nurses is not nearly equal to the demand in this country. Owing to the poor pay and to a regulation which exists in the principal hospitals that a person may not commence training until the age of 23, few are coming forward to join the nursing profession. The situation is extremely awkward, as although the hospital authorities allow that nurses are underpaid, the financial conditions of the hospitals is such that they cannot afford to pay more.

Conference on the Care of Cripples.—A joint conference of the Invalid Children's Aid Association and the Central Committee for the Care of Cripples was held in the Guildhall, London, on November 16 and 17. Among those who spoke on the second day was Mr. Douglas McMurtrie, president of the Federation of Associations for Cripples in New York City. Mr. McMurtrie's speech was greatly appreciated by the audience. He said in part that in New York they had started a district nursing association exclusively for crippled children. These nurses were soon found to be the best agency for the early discovery of such children. Recently they had also arranged for certain mothers of crippled children to notify the association of any children living within their area whom they suspected of having a deformity, a fee of 25 cents being paid for each case; the child was then visited by the nurse. Through the newspapers they had organized a corps of voluntary teachers for home-bound children; this work, he was pleased to say, had been taken over by the city education authorities. The difficulty of find-

ing employment for these cripples confined to their homes had been successfully tackled; they were taught to carry out a subdivided process, often of some little known trade. Very few were self-supporting, but the work they were able to do meant a lot to them. The association found that their employment bureau was in one way almost as good as a training school. It had been used to make a survey of occupations and processes available in New York for cripples, and in experiments of employment of cripples in different processes.

He thought that the provision for cripples by public authorities in England was better than that made in America, but considered that a campaign to educate the public to accept the cripple as a worker would be of service to us. Mr. R. C. Elmslie said that his criticism was that institutions provided by education authorities in England were not founded for combined surgical treatment and education. Much improvement had taken place in this respect but there was still a lack of appreciation of what can be done for certain deformed children. He urged that convalescent homes should be placed under proper surgical and educational inspection. He wanted the Ministry of Health or the Board of Education to ask for adequate surgical inspection of such institutions.

Obituary.—On December 2 last, Sir Frederick Taylor, Bart., M.D., F.R.C.P., passed away at the age of 73. He became a member of the Royal College of Surgeons in 1868, and received the degree of M.D. of London University in 1870. He took the membership of the Royal College of Physicians in 1872 and was elected a Fellow in 1879. He was appointed to the staff of Guy's Hospital early in life, and at the time of his death was one of the consulting physicians. The two chief appointments of his later life were the presidency of the Royal College of Physicians and the presidency of the Royal Society of Medicine. Perhaps he was best known, at least outside his own country, as the author of "The Practice of Medicine," a true medical classic, the eleventh edition of which appeared in 1918.

3. The Minor Role of the Conduction Apparatus in Slowly Progressive Deafness.—Francis P. Emerson holds that there is always a nerve element in every case of so-called conduction deafness of the progressive type. The prognosis in regard to restoration of hearing is dependent upon the perception and not upon the conduction apparatus. Toxic deafness and that due to beginning nerve degeneration cannot be differentiated by any aural examination. Silent areas or islands of deafness are quite common in chronic catarrhal otitis media. The etiological factor is usually active in the lymphoid tissue as a chronic infection with acute exacerbations. In some cases of long-standing deafness it would seem necessary to reeducate the aural perception centers by exercises, after all sources of infection have been eliminated.

10. A New Site for Smallpox Vaccination. I. H. Goldberg.
6. Lumbar Puncture in Diseases of Children.—H. Apfel gives the following indications for lumbar puncture in a child: (1) For the relief of pressure symptoms. (2) For the purpose of differential diagnosis. (3) For the purpose of administering therapeutic aid intraspinally. Under the first group come a large number of conditions, in both infancy and childhood—notably hydrocephalus; meningitis due to some type of organism against which there is no specific antidote; acute infectious diseases, pneumonia for example, complicated with serous meningitis, or so-called meningismus. Considering the second group, every time one is called upon to make a differential diagnosis between an acute disease complicated with meningismus and purulent meningitis, or when one is confronted with the problem of deciding whether the condition is tuberculous meningitis or poliomyelitis, whether a given case may present symptoms of cerebral lues, calling for colloidal gold and Wassermann tests on the spinal fluid, then one's mind immediately reverts to lumbar puncture. As for the third group of indications, one need only refer to the difference in the mortality rate of cerebrospinal meningitis previous to 1890, and at the present time to convince the most skeptical as to its benefits as a therapeutic measure. The operation is simple, with practically no danger to the patient. Its usefulness for diagnostic purposes is indispensable, and it should be resorted to early in the course of the illness. The technique should be learned by all physicians.
8. The Physical Signs of Pneumonia in Children.—Samuel A. Blauner holds that the diagnosis of either pneumonia or empyema, as a rule, is not difficult. It is only necessary to unlearn some of the false teachings of textbooks and to remember that to obtain bronchial breathing one must have a uniform consolidated area extending to the hilum of the lung or in communication with a bronchus, and that the apparent variation in the physical signs results from the failure of the original tracheal breathing to reach a uniform consolidated area and be transmitted unchanged.
10. A New Site for Smallpox Vaccination.—I. H. Goldberg considers the inner and back side of the arm as the ideal location for the inoculation of smallpox virus, for the following reasons: (1) It leaves no visible scar. (2) It does not keep children from having their daily tub bath while the vaccination is passing through its various stages. (3) There is little or no exposure to infection from outside sources of infection. (4) It minimizes possibilities of trauma. (5) There are no infiltrations, extensive indurations, sloughings, or extensive scars.

1. **The Nature of Arthritis and Rheumatoid Conditions.**—Ralph Pemberton presents in this communication certain points of a clinical nature not included in a previous report (*Archives of Internal Medicine*, March, 1920, 231) based on the study of 400 cases of chronic arthritis in the army. Certain theoretical aspects are also discussed in the effort to narrow the conceptions of the problem, and hence of the field studied. Although the importance of focal infection was abundantly illustrated and is not in any sense to be minimized, the subjects of this study showed an interesting and large independence of it. It became clear that, in these younger subjects, focal infection played an analogous but lesser rôle as compared with its relation to the bulk of cases encountered in civil life. Added importance was given to the view that with chronicity the results of the removal of focal infection become less noteworthy, although there are important exceptions to this. It is pointed out that in a regrettable number of chronic cases, and in some early instances, the removal of focal infection may be of no avail whatever. The important rôle, as shown by the statistics of the series, played by exposure and wet, and the evidence adduced by studies of the sugar tolerance, strongly suggest that this disease is not infrequently referable to causes other than focal infection. Many instances in the series were caused by dysentery, influenza, pneumonia, and other conditions which added importantly to the appreciation of the fact that infections of diffuse types may inaugurate the same results, although the most frequent type is that resident in teeth, tonsils, and so on. It is clear, however, from some of these cases, that the arthritis may be referable not solely to the apparently originating factors of dysentery, influenza, or exposure, because some cases in which these were the well punctuated causes made a later significant improvement when demonstrable foci were removed. It therefore appears that foci otherwise inoperative may be made operative by a severe illness. The only alternative to that is that they themselves have been actually produced as the result of this illness. The probable mechanism here is that the original disease or exposure induces the situation which in other cases foci themselves may cause; on the basis of this situation, foci then act to perpetuate conditions for which they were not originally responsible. Various questions involved in what the writer calls the "substratum of pathology" are discussed. For example, it was found that in 20 per cent. of the cases basal metabolism was below normal. The relation between the intake of food and the incidence and perpetuation of the symptoms of chronic arthritis was studied. Although the respective rôles of the three foodstuffs, protein, fat, and carbohydrate, have not been entirely worked out, the evidence strongly suggested that at least carbohydrate was caught up in some important way in this connection. Arthritides show a lowering of sugar tolerance more or less proportional to the severity of the disease. There was found in all these observations experimental corroboration of the premises on which the dietetic therapy is based. Among other phases of the subject discussed are the cause of delayed onset; significance of frequency with which muscles and joints are affected; factors affecting the oxidative function; a working hypothesis, and general line of treatment. Treatment should be postulated on the removal of the exciting cause first, when this is possible. One of the outstanding lessons derived from the study of arthritis among large numbers of soldiers was to the effect that various accessory lines of treatment could be profitably combined, although often unavailing alone.

5. **The Surgical Treatment of Typhoid Carriers.**—Edwin Henes, Jr., from the study of 183 patients who had contracted typhoid fever at the detention camp for interned alien enemies at Hot Springs, N. C., who were sent to U. S. General Hospital No. 12 at Baltimore, N. C., where he was on duty at the time, the following conclusions are drawn: (1) Cultural examinations of the duodenal contents are indicated in all cases during convalescence from typhoid fever. (2) Cholecystitis is a frequent complication of typhoid fever. (3) Persistent infectiousness following typhoid fever is usually the result of cholecystitis. (4) A gallbladder may continue to be infectious without the usual manifestations of a cholecystitis. (5) Cholecystectomy, with complete

excision of the cystic duct, will cure the great majority of typhoid carriers. (6) Radical (surgical) treatment of complicating cholecystitis is to be considered. The likelihood of a carrier state is thereby greatly diminished, and the probability of future gallbladder trouble obviated. 7. Examination of the duodenal contents should imply an examination of the contents periodically aspirated and cultivated during the course of twelve or twenty-four hours. Three such consecutive, negative examinations, made at weekly intervals, are the criterion of a cure of persistent infectiousness. (8) Typhoid fever is a preventable disease. The incidence of the disease has been astoundingly decreased by the use of prophylactic inoculation, and more can be accomplished along these lines. But endemic typhoid will continue to exist just so long as there is failure to detect persistent infectiousness. The researches at Biltmore show conclusively that the gall bladder is the seat of continued infectiousness, and an intelligent cultural examination of the duodenal contents can definitely detect infectiousness. No case of typhoid fever is to be judged free from infectiousness until it can be conclusively shown that the gall bladder and its contents are free from typhoid bacilli. In the event of persistent infectiousness, the indication is definite and absolute—cholecystectomy.

1. **Some Aspects of Mental Hygiene.**—E. Farquhar Buzzard, in his presidential address delivered to the Section of Psychiatry, Royal Society of Medicine, on November 9, discusses the value of psychoanalysis; the origin of "nerves," the confusion of ethical and psychological issues; the creation of environment for the advancement of mental hygiene; multiple factors in mental hygiene, and the value of rest and thought. In recapitulating he calls mental hygiene a young plant which is worth cultivating, and which is full of promise. Its growth, he holds, must be promoted: (1) By no longer misnaming mental disorders as nervous. It is perhaps time to be courageous and to call institutions hospitals or clinics for minor mental disorders in preference to functional nervous disorders; (2) by getting rid of the confusion between ethical and medical principles as they affect health; (3) by teaching elementary principles of psychopathology and psychotherapy to students in order that the general practitioner may take a prominent part in maintaining the mental health of individuals; these subjects, being more important than much that the student is called upon to know, should be introduced into the syllabus for examinations and questions set upon them; (4) by obtaining general recognition for the multiplicity of factors concerned in producing mental as well as other disorders; (5) by giving due prominence to fatigue as a factor in psychopathology and to rest in psychotherapy; (6) by encouraging education in thinking as an important preventive measure.

2. **The Influence of the Great War on Modern Surgery.**—Charles F. M. Saint recapitulates the beneficial influences of the war on modern surgery as follows: (1) The chief benefits arising from the popularization of already existing procedures are blood transfusion, nitrous oxide and oxygen anesthesia, bone and nerve surgery, and orthopedic constructive work. Though bone surgery has been merely referred to, mention must be made of the Thomas splint, which achieved a well-earned and well-deserved popularity. (2) Among the "re-births" might be included a considerable portion of the present views of shock, the ligature of the bleeding point in arrest of hemorrhage, secondary suture of wounds, and excision of wounds and primary suture. (3) Finally, of "new discoveries and their applications" one has referred to bipp, flavine, ambrine, and the calipers employed for extension in cases of fracture. It will be readily seen, therefore, as the writer postulated at the outset, that the chief benefits in civil prac-

tice attributable to war surgery are intimately associated with that branch of civil surgery which is comparable to that of war—namely, injury, in its various relationships.

3. **Commentary on a Case of Hystero-Epilepsy with Delayed Puberty Treated with Testicular Extract.**—T. C. Graves reports a case observed in a male twin, emphasizing the association of the two conditions and the combination of physical and psychological factors in the causation of mental disturbance. Undoubtedly a practical joke (being tumbled out of a hammock while asleep) was the starting point of his "escape reaction," inducing fear processes which subsequently operated whenever associations were aroused, e.g. at eventide or when placed in company with strangers. One would deduce that on these occasions a hypersecretion of adrenaline occurred not equilibrated by the internal secretion of the gonads owing to their lack of development. In this case a real psychotherapeutic effect appears to have been produced, especially when one notes the placebo effects of drugs given prior to admission, and evidently the psychophysical vicious spiral has been broken—the gain in weight alone testified to this. The intermittency of the medication and the use of one and then two tablets was deliberate. Although the difference in dosage is small, it is noteworthy that two observers found the same thing—namely, a diminution in the intensity of the symptoms when one tablet was administered and a non-recurrence of the condition when fully under the influence of two tablets. These observations, together with the loss of muscular weakness of the right limbs and the rapid clearance of all the neurological signs, are held by Graves to be hardly the results of a mere coincidence.

1. **Orthopedic Surgery in Relation to Hospital Training.**—Sir Robert Jones suggests the following group of cases which the modern orthopedic surgeon should be prepared to treat: Fractures—recent, malunited, and ununited; congenital and acquired deformities of the extremities; paralysis of the extremities; diseases, derangements, and disabilities of the joints, including the spine, wry-neck, and those conditions included under the general term "bone-setting." According to the scheme which he suggests for the orthopedic department of a general hospital, (1) the definition of orthopedic surgery on the lines suggested should be adopted. (2) The general surgeon should be allowed to treat any of such cases as he desires. (3) The work of the orthopedic surgeon should be strictly limited by the definition. (4) No orthopedic department should be confined to the treatment of outpatients; it should be a complete unit with beds commensurate to outpatient demands. The staff should consist of an orthopedic surgeon, an orthopedic registrar, a house surgeon, dressers, and clinical assistants. Because of the time required to train nurses for orthopedic work, they should be given security of tenure. In a hospital of 300 surgical beds 40 should be reserved for orthopedic cases. These beds should be segregated, and beds in the country should be provided for children. Both undergraduate and post-graduate instruction in orthopedics should be part of the training of those who would practise this branch.

4. **A Note on the Treatment of Cutaneous Erysipelas with Brilliant Green.**—Joseph E. Adams does not at-

tempt to present scientific data to confirm his clinical impression as to the usefulness of brilliant green in cutaneous erysipelas. Nevertheless, since his observations are fairly numerous, he does not hesitate to recommend this simple method. In a dozen cases treated the average time for subsidence of the attack was just five days. There has been no mortality in the whole series, though recrudescence occurred in two cases. The obvious objection to the use of brilliant green is that it stains whatever it comes in contact with, whether it be the skin of the patient, the hands of the nurse, or the bedclothes. As far as he is aware brilliant green possesses no toxic properties. Both iodine and picric acid are open to objection on this ground. The method employed has been to paint the affected area with a 5 per cent. aqueous solution once a day in mild cases and twice a day in severe cases. No dressing has been applied except a piece of lint on some parts of the body to prevent staining of the bedclothes. When the eruption has subsided the discoloration can be removed in three or four days by vigorous washing, preferably with ether soap. Possibly it would be wise to apply the solution over rather a wider area than that actually involved—for, say, an inch outside the advancing edge—but so far he has not done this.

3. **Miner's Nystagmus: Suggestions for Its Prevention.**—D. Lechmere Anderson calls attention to the two types of nystagmus which occur in miners, namely, the minor, latent or transitory, mild in character, and degree, and the major, incapacitating, grave type. In each there are two principal personal factors in production: (a) Refractive errors, structural and other defects of the eye; (b) abnormalities of the neuromuscular mechanism of the eyeball. When the conditions are slight the minor type as a rule results, when marked, the major type. Great improvement has been made with respect to defective illumination, one of the exciting causes, but no advance has been made in the removal of the personal predisposing cause of the disease, and without this one can hardly hope for success. It seems essential to establish a refraction standard for miners, and thus prevent men from taking up a form of employment totally unsuited to their physical powers. By this means could be eliminated the major cases of disease from the mines, and although the minor types may occur they will be reduced in severity and in frequency. The standard which the writer suggests for admission to pit life is the ability to read Snellen 6/18 at twenty feet with each eye separately, or Snellen 6/12 (at least three letters) with both eyes at twenty feet. In the event of failure to pass the above tests the man would be referred to the certifying factory surgeon, who should have a knowledge of eye work. With a considerable amount of hypermetropia or myopia (which might be arbitrarily fixed at 1 D) the man's attention would be directed to the abnormality, and such abnormality noted on the register. Although he might not be excluded from work as a miner, he would be advised to seek other employment, and to wear suitable glasses. If the error of refraction exceeded 1 D hypermetropia or myopia, or if astigmatism was present, the man would be excluded from work as a coal miner. These suggestions as to standard are only intended as provisional, and could be modified in the light of experience.

5. **Treatment of Rheumatoid Arthritis by Vaccines.**—H. Warren Crowe bases this communication on observations in one hundred and forty-three cases. The basis of the treatment in this series was the hypothesis which

the writer put forward in 1914, to the effect that rheumatoid arthritis was primarily due to an organism, the *Staphylococcus epidermidis albus* (var. *deformans*); that, just as in tuberculosis, there were present in the majority of cases secondary infections, with or without a local focus; that it was these secondary infections where the radical treatment of a local infective focus, with or without vaccines, resulted in amelioration or cure of the disease, the explanation was that the system, relieved of some of its microbial enemies, had then been strong enough to overcome the primary organism; and, finally, that *M. deformans* or its toxin acted primarily on the nervous system and was responsible for the neuropathies which are the predominating, if not the sole, symptom of uncomplicated rheumatoid arthritis. All the cases were treated, without exception, on this hypothesis, and no other treatment was given to any of the successful cases, with the exception of simple symptomatic measures, such as occasional aspirin for the relief of pain and latterly some mild hydrotherapy. Deformans vaccine was given in every case. Although some nine years have elapsed, the same vaccine is still in use with no apparent deterioration. It was prepared originally from two strains. This vaccine was either combined or given alternately with autogenous vaccines when a definite infective focus was found, or if the urine was infected. When the symptoms were such as to suggest a coincident rheumatic infection, then a streptococcus vaccine was also given, prepared from a large number of strains isolated from severe cases. None of the strains were isolated from joints, but from such conditions as acute nephritis with joint swellings and strepto-bacteriuria, and acute tonsillitis and rheumatism. No pyogenic streptococci were combined in the vaccine, but all conformed to one or other of the alimentary types. Among the sixty-two cases of which the notes are fairly complete, only 21 per cent. failed to respond in some degree. Other 95 per cent. improved but slightly or relapsed early; 7.0 per cent. may be said to have been cured for the time being as far as cure was possible, and of these it is known that 15, or 25 per cent. of the total, still maintain their position. From recent experience it is suggested that those who have relapsed would have regained their health under further vaccines, and only the war, in the majority of cases, prevented this. No other method of treatment, in the writer's opinion, can show anything like these results in rheumatoid arthritis.

6. The Treatment of Ascites by Drainage. Sir John O'Connor.
2. Observations on Subacute Infective Endocarditis.—Thomas F. Cotton states that there are in the United Kingdom about 80,000 men receiving pensions for some cardiovascular affection. In the London area there are, roughly, 8000 pensioners with some cardiac disability, and 1200 to 1500 of these have structural disease of the heart. All of them come before the Resurvey Boards for re-examination and assessment at intervals of nine to twelve months. They are called up on special days, and all those with signs of structural disease are seen by a heart specialist. During the past year the writer has acted as heart specialist at two Resurvey Boards. Such cases as required treatment or further examination he referred to the Cardiographic Department at University College Hospital. At this clinic they receive outpatient treatment or are admitted to the wards of the hospital. Here he has been able to observe during the past year and a half a large number of selected cases presenting signs of structural disease of the heart. The most striking clinical feature of this clinic has been the large number of subacute infective endocarditis cases. From September, 1919, to June 1, 1920, there were admitted as outpatients 159

pensioners presenting signs of aortic regurgitation, 136 with signs of mitral stenosis, and 65 with mitral stenosis and aortic regurgitation. In 30 of these the diagnosis of subacute infective endocarditis was made, and 11 were suspected as having this disease—that is, 8 per cent., and possibly more, of 360 patients with gross valvular disease had subacute infective endocarditis. The observations recorded in this paper are based on a clinical study of 15 of these cases, together with a larger group of 40 patients with subacute infective endocarditis, whom he has had under his care while in charge of the clinical services at the Sobrão Military Hospital, Colchester. From this study he concludes that subacute infective endocarditis is not a rare disease. It is seen in 8 per cent. of patients with signs of gross valvular disease attending a special heart clinic. The signs are easy to recognize. In the diagnosis chief reliance should be placed on the following signs: Gross valvular disease, pallor, enlarged spleen, and clubbing of the finger-tips. Aortic regurgitation is the type of valvular disease usually seen in this disease; it is rare to find the mitral valve alone involved. The course of the disease from the onset of symptoms is usually less than fourteen months; death may occur within two months of the onset of symptoms. A bacteriological examination of the blood is useful in confirming the diagnosis. Without such an examination the diagnosis may be made with certainty. The disease is always fatal.

4. Antimony in the Treatment of Leprosy.—F. G. Cawston reports the further experience in the treatment of leprosy by means of intramuscular injections with Oppenheimer's colloidal preparation of antimony (oscol stibium), remarkable improvement having been noted in some patients thus treated. Two lepers treated by this method form the basis of this report. On admission both were showing active signs of the disease, with numerous ulcers on the fingers and toes. Although no further treatment had been given for over a month, there had been no recurrence of the signs of leprosy, and the ulcers had completely dried up.

3. The Importance of Extending Knowledge Concerning Child Hygiene.—Richard A. Bolt calls attention to the fact that eighty private or semi-private organizations, purporting to be national in scope, have announced in their programs that they are touching "child welfare" at some point. The very term "child welfare" has become a fetish which organizations, numerous and diverse, are invoking to command public sympathy and support. Propaganda, good, bad and pernicious, has been sent out from practically all the so-called "national organizations." Newspapers and magazines have sensed the popular demand and supplied a miscellaneous assortment of articles bearing on child welfare. The Government departments have put out a considerable amount of valuable material on child welfare, but this at best reached only a fraction of the people who should be reached. It is true that an ever-increasing number of medical men are beginning to appreciate the importance of socio-medical work for children, but the writer asks the question, "Why is it that public health nurses, social workers, dietitians, psychoanalysts, health crusaders, health fairies and health clowns have secured such a wide and attentive hearing in imparting lessons of child health, while physicians have remained content with private interviews in their offices and hurried instructions at child welfare centers?" It is an untenable position for the medical profession to take, Dr. Bolt says, that important instruction, even in the most simple matters of child hygiene, should be left entirely to those outside the profession.

Book Reviews.

ELECTRICAL TREATMENT. By WILFRED HARRIS, M.D., F.R.C.P., Senior Physician and Lecturer on Neurology, St. Mary's Hospital. Third Ed. New York: William Wood & Company, 1920.

In contrast with the earlier editions, the subjects of radium therapy and x-ray treatment have been omitted. Only nominal space is devoted to high frequency circuits, and this in the chapter on static electricity. The aim is thus realized of writing a book to deal almost exclusively with the galvanic, faradic and sinusoidal currents and the affections in which they are indicated. The number of pages of the abridged work is 354, of nearly solid text, the illustrations being limited to 24. The amount and variety of work which is practicable with a portable galvanic or faradic battery or an apparatus of the multostat type for office use and operated by the street current, may be visualized by a survey of the contents of the book.

RETRAINING CANADA'S DISABLED SOLDIERS. WALTER E. SEGSWORTH, M.E., Formerly Director of Vocational Training, etc. Ottawa: J. de Labroquerie Taché, 1920.

The more technical chapters in this volume are devoted to curative workshops, ward occupations, interviewing, industrial retraining, industrial surveys, medical aspects, care of the blind, results and after care. Others deal with the scope and history of the movement, the organization, statistics and costs. There are appendices devoted to work of the same class in other countries, selected bibliography, the hours per day or week required for training, and the pay and allowances during training.

THE LINK BETWEEN THE PRACTITIONER AND THE LABORATORY. A Guide to the Practitioner in His Relations with the Pathological Laboratory. By CAVENTISH FLETCHER, M.B., B.S., M.R.C.S., L.R.C.P. and HUGH MCLEAN, B.A., B.C., D.P.H., M.R.C.S., L.R.C.P. New York: Paul B. Hoeber, 1920.

This is a small book which is intended to suggest what laboratory procedures are best suited for the diagnosis of various diseases and to inform the practitioner as to the most desirable methods for securing specimens and sending them to the pathologist. There is placed first an alphabetical list of diseases and conditions under each of which is given the examinations recommended. As a rule the suggestions are admirable. There are a few omissions and in some instances the English practice is apparently different from ours. The authors recommend the use of 50 per cent. alcohol for the preservation of tissue for histological examination while we are much more apt to use 10 per cent. formalin. The determination of the uric acid content of the blood is not mentioned under gout though that of the urine is. Under the heading of asthma there is no mention of the tests for the detection of hypersensitiveness that are being done so extensively at the present time. Under the heading of pleural effusion there is no mention of the liability of these fluids to coagulate. It is of great advantage to add a small amount of sodium citrate to these specimens in order to prevent the formation of the fibrin clot. The authors apparently have more faith in the Cammidge reaction than is found in this country. This is a very handy little volume and might prove of a good deal of assistance to many practitioners especially when they are situated a long way from a laboratory.

PATHOGENIC MICROORGANISMS. A Text-Book for Physicians and Students of Medicine. By WARD J. MACNEAL, Ph.D., M.D., Professor of Pathology and Bacteriology and Director of the Laboratories in the New York Post-Graduate Medical School and Hospital, New York. (Based upon Williams' Bacteriology.) Second Edition. Philadelphia: P. Blakiston's Son & Co., 1920.

The second edition of this work has been extensively revised and somewhat enlarged but its old friends will find that its plan has remained unchanged. To those who are unfamiliar with the book it may be said that it is a rather condensed though very complete presen-

tation of the subject of bacteriology suitable for the use of the student or practitioner. It perhaps may not be sufficiently detailed and extensive for the bacteriologist but it contains all of the information that the average physician is apt to need. It is a very convenient and satisfactory work.

PUBLIC HEALTH LABORATORY WORK (CHEMISTRY). By HENRY R. KENWOOD, C.M.G., M.B., F.R.S., D.P.H., F.C.S., Chadwick Professor of Hygiene and Public Health, University of London. Seventh Edition. New York: Paul B. Hoeber, 1920.

WITH the development of the importance of bacteriology in Public Health work it has been found necessary to treat the subject in a separate volume. Therefore in this edition, this volume deals almost exclusively with the chemical side of the subject. It is announced that a companion work dealing with microbiology is being prepared. The topics presented in this book are the examination of water, sewage, sewage effluents, soil, air, food and disinfectants. This edition has been amplified and advantage has been taken of the recent advances in the subject. The methods have been well selected and described and there are numerous illustrations. The work will be a great help to anyone doing this type of investigation.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles by Leading Members of the Medical Profession Throughout the World. Edited by H. R. M. LANDIS, M.D., Philadelphia. Volume II. Thirtieth Series, 1920. Philadelphia and London: J. B. Lippincott Company, 1920.

IN this number of the Clinics there are eighteen contributions which go to make up a volume of over three hundred pages. Five clinic reports present a number of interesting cases for the consideration of the readers. L. Thompson has a complete and profusely illustrated article on the skin lesions of syphilis. Magnuson and Coulter have contributed an article under the title of Industrial Surgical Clinics that presents in a very striking manner the problems which such clinics are called upon to solve and the importance of the proper method of handling the patients. A number of other contributions offer topics of general interest.

MATERNITAS. A BOOK CONCERNING THE CARE OF THE PROSPECTIVE MOTHER AND HER CHILD. By CHARLES E. PADDOCK, M.D., Professor of Obstetrics, Chicago Post-Graduate Medical School. Chicago: Cloyd J. Head & Co., 1920.

THIS volume of 210 pages consists of two parts devoted respectively to the mother and the infant during the first two years of life. It is intended to be placed in the hands of the prospective mother as a guide during the gestational and lactation periods. It is not at all intended for the practitioner. Although not announced on the title page the book has already gone through two editions. There are numerous unnumbered original illustrations. Recipes of various kinds are given in an appendix. The present edition has been much improved by incorporating new data.

THE NATURE OF ANIMAL LIGHT. By E. NEWTON HARVEY, Ph.D. Philadelphia and London: J. P. Lippincott Company, 1920.

THE author is professor of physiology in Princeton University and the volume is one of a series of monographs on experimental biology. There are seven chapters devoted respectively to light-producing organisms, luminescence, physical nature of animal light, structure of luminous organs, chemistry of light production (2 chapters) and dynamics of luminescence. No doubt the interest of the public will center largely on the relation of animal luminescence to electronic phenomena under which fluorescence and phosphorescence are placed by some authors and which are excited in inert matter of bombardment with cathode rays. Animal luminescence, however, is seen in many unicellular organisms as bacteria and fungi. The claim that light rays from animals can pierce opaque objects and affect a photographic plate has not yet been proved and the author expressly states that animal light is simply ordinary light save that it is more intense and has a more extensive spectrum.

Society Reports.

SOUTHERN MEDICAL ASSOCIATION.

Fourteenth Annual Meeting, Held at Louisville, Kentucky, November 15, 16, 17, and 18, 1920.

THE PRESIDENT, DR. E. H. CARY, OF DALLAS, TEXAS, IN THE CHAIR.

Fluid in the Pleural Cavity.—Dr. W. W. RUCKS of Oklahoma City drew the following conclusions: (1) The pleura bears a close analogy to the peritoneum, inasmuch as its major involvements are secondary to disease in the underlying organs. (2) The character of pleural effusion is determined by the nature of the primary infections in the lungs. (3) There is a selective time for its removal by operation, which is not upon its immediate formation, but a lapse of sufficient time should be allowed for the formation of resisting bodies, improvement or recovery from pneumonia, and the protection by adhesions of the remainder of the breathing space from the effect of atmospheric pressure when the chest wall is opened.

Direct Aspiration of the Contents of the Biliary Tract Through the Duodenal Tube.—Dr. SIDNEY K. SIMON of New Orleans stated that among the 30 cases upon whom he had employed this method to date, in 10 there was a prompt amelioration of pain and other local symptoms, along with the removal of toxic features. In one case the temperature curve receded from a height of 103° to normal after the second aspiration. (This case, incidentally, had remained free of further disturbances for a period of three months.) In one other case coming under his observation—a lady who had been a victim of chronic arthritis for several years and who had been deprived in due course of teeth and tonsils without effect upon the arthritic condition—a ten day nonsurgical drainage of the gall tract produced immediate and apparently permanent relief. Other illustrations might be cited of clinical benefits derived among the series of 30 cases, did time permit. The purpose sought at this time, however, was merely to focus attention upon the diagnostic and therapeutic possibilities involved in the method, with the hope that a more general interest and a wider application of the procedure might be stimulated among the profession at large. In seven of the cases followed by him, autogenous vaccines were prepared by Dr. Lanford and applied in the usual manner. His experience with the vaccine therapy in this field did not appear promising, although he did not feel justified as yet in formulating any definite conclusions in this regard.

The Treatment of Neurosyphilis.—Dr. ALBERT KEIDEL of Baltimore, Maryland, said that intraspinal therapy was made necessary by the inaccessibility of foci of infection to substances in the blood stream. The treponemas appeared to elect situations remote from blood stream influences. They were tissue organisms because the cultural conditions in the lymphatic system, particularly the intercellular spaces, were more favorable to their existence. Herein lay the main obstacles to successful treatment. The added factor of vascularities and perivascularities induced by the presence of the organisms greatly increased this difficulty. In general, it might be stated that failure of general intensive treatment to cure neurosyphilis might be due to the degree of perivascularitis present at the time treatment was begun, which explained the greater success in that form of treatment early in the disease. It was also probably due to this factor that differences of opinion arose as to the relative merits of ordinary antisyphilitic treatment and the more direct methods of the intraspinal type. If the personality of the vessel wall was not too greatly interfered with by the perivascular reaction, substances in the blood might escape into the tissues in sufficient concentration to reach the treponemas and obliterate them. If this were not the case, no amount of intravenous medication would suffice. The application of intraspinal therapy, therefore, should be restricted to those early cases which proved refractory to treatment by the ordinary routes early in the infection, and to all cases with organic pathological changes produced by long contact of the organism with the tissues. Among these later cases treatment

by the ordinary routes would often succeed in obliterating serologic abnormalities, with marked clinical improvement, but the possibility of isolated foci of infection remaining undisturbed in areas not involved in the clinical picture made the addition of intraspinal therapy desirable as an adjunct to the general treatment. In estimating the degree to which intraspinal treatment should be resorted to, one should be guided by the differential diagnosis and by the amount and rate of response to ordinary treatment.

Neurophilic Myelocytes in the Cerebrospinal Fluid of a Patient Suffering from Myeloid Leucemia and Their Significance for the Diagnosis of Myelocytic Infiltration of the Leptomeninges.—Dr. LEWELLYS F. BARKER of Baltimore drew the following conclusions: (1) In a single case it has been possible during life to demonstrate in the cerebrospinal fluid the presence of cells of leucemic origin (myelocytes and perhaps myeloblasts). (2) In no other case thus far reported has the presence of leucemic cells in the cerebrospinal fluid been described during life. (3) In the few instances in which lumbar puncture has been done in leucemia, the cerebrospinal fluid has been negative, or has shown merely a trace of blood or an increase of globulin. (4) The presence of cells of leucemic origin in the cerebrospinal fluid probably indicated a leucemic infiltration of the leptomeninges. (5) The majority of nervous complications in leucemia are not due to a leucemic leptomeningopathy, but to epidural infiltration, to infiltration of the nerve roots or of nerve ganglia, to infiltration of the nervous axis itself, or to hemorrhages or degenerations, or inflammations.

Etiology and Diagnosis of Nephritis.—Dr. J. B. McELROY of Memphis gave the diagnostic features as follows: (1) Nephritis occurred most frequently from 40 to 50 years of age and in men. (2) The good general condition of benign hypertension rapidly declined and soon presented the characteristic cachectic condition of chronic nephritis. (3) The disease ran its course as a cardiovascular renal disease. The cardiovascular symptoms, as compared with benign hypertension, were characterized by a tendency to greater severity. (4) The blood pressure from the beginning was high and constantly maintained, showing the highest values. (5) The cardiac hypertrophy was marked, came on early, and here was found the largest hearts. (6) Edema, when present, was of cardiac origin. (7) The blood showed marked secondary anemia in contrast to benign hypertension. (8) There was mycturia, with day and night polyuria, and the urine showed a low specific gravity, albuminuria, and cylindruria of moderate grades. (9) Papillitis and neurorinitis were the rule and afforded a certain indication that the case did not belong to the type of benign hypertension, although the kidney functional test might show little or no impairment. (10) Impairment of kidney function was the chief characteristic of this type. This varied from the slight to the most severe, similar to the last stage of chronic diffuse glomerulonephritis with kidney insufficiency. (11) If death did not occur earlier from the cardiovascular component of the disease or a pulmonary complication, the end results were from true uremia as in the end stage of chronic diffuse glomerulonephritis. Eclamptic equivalents were prominent as in benign hypertension, the psychical symptoms tending to be more severe. Eclamptic uremia might rarely occur.

The Importance of Eye Examinations in Nephritis.—Dr. ADOLPH O. PRINGST of Louisville emphasized the frequency of retinal involvement in nephritis, especially in the chronic interstitial type of cases, though he would stress the point that negative ophthalmoscopic findings in cases of suspected renal disease would in no way exclude the possibility of the presence of an incipient renal disease. The frequent use of the ophthalmoscope in all cases in which kidney trouble was suspected should be encouraged, as well as a careful inspection of the retina of every presbyopic patient who presented himself to the oculist for the correction of refractive errors, as early retinal changes were often visible in general arteriosclerosis and chronic nephritis even before a uranalysis would reveal anything to indicate a kidney lesion. Through the early detection of retinal changes and the institution of hygienic, dietetic, and therapeutic measures, the general condition of the patient might be improved and so-called prealbuminuric

retinal changes might clear up. In the well developed cases of reinitis with effusions, with or without hemorrhages, an ophthalmoscopic examination was important on account of the prognostic significance of nephritic reinitis both as regards the life of the patient and the ocular function.

Nephritis in Childhood.—Dr. L. R. DEBUYS of New Orleans said that the chronic cases of nephritis during their acute exacerbations were treated just as were the acute cases of nephritis. Otherwise, they received the same treatment as did the cases of chronic nephritis in the adult. Two factors stood out in the treatment of chronic nephritis in children, (1) to treat the etiological factors properly so as to eradicate the cause or retard the progress of the disease, and (2) to remove the conditions which predisposed to the acute exacerbations. Regulation of rest, exercise, and diet and the proper administration of tonics were of prime importance in the treatment of the chronic cases of nephritis. In those cases in which dropsy was present a salt-free diet was indicated; the other symptoms were treated as in the acute cases. In cases resisting treatment and growing progressively worse decapsulation of the kidney might be practised. This was often followed by relief, which, however, was liable to be only temporary, though complete recoveries had been recorded.

Treatment of Chronic Nephritis.—Dr. W. H. WITT of Nashville stated that in a general way the prognosis in a nephritic was a composite of a chemical study of the blood and urine, color elimination, sustained or varying specific gravity of the urine, the blood pressure, and, not least, the willingness of the patient to accept advice as to diet and mode of living. It was a disease that was compatible with years of usefulness if discovered in its early stages. It was one that must not be over-treated, but rather managed or directed. We should not overrate its seriousness nor put a too high estimate on what we could do to modify its course. There was hardly any disease in the management of which the personality of the physician counted for more, especially when it came time to curtail the patient's privileges—when he came to a full realization that he had a disease from which he could not hope for recovery. Consequently one could often say to a nephritic that his disease was compatible with many useful years, depending largely, of course, on his status when the diagnosis was made.

Thrombosis of the Coronary Arteries.—Dr. J. E. PAULLIN of Atlanta said that early diagnosis was of the greatest importance. Absolute rest in bed for days and weeks was necessary. The only hope for recovery lay in securing for the infarcted area as rapidly as possible an adequate supply of blood through its collateral circulation; the ability to do this depended on the condition of the unobstructed artery, the extent of the anastomosis and the size of the infarct. Miller and Matthews had clearly shown in their experimental work that the death rate in dogs following ligation of the coronary artery was much lower where the animal received digitalis or strophanthus, and that these drugs were useful in promoting and increasing the collateral circulation. Might one not assume, then, that the same condition would obtain in man and that by the administration intravenously or hypodermically, either of strophanthus or digitalis, that we were helping the heart to establish this collateral circulation. He believed this procedure was of great value in one of his cases. To be of value this remedy must be used early and in sufficient dosage to get a quick effect. He had seen no good result from the use of nitroglycerin or the nitrites. Morphine in sufficient dosage to relieve pain was absolutely necessary.

The Significance of Vertigo.—Dr. DOUGLAS VANDERHOOF of Richmond, Va., stated that we must thoroughly understand that the labyrinth was the sense organ of equilibration. Vertigo, from whatever cause, was essentially an ear study, and was always due to some disturbance of the vestibular apparatus. Disturbances of the vestibular apparatus could be definitely analyzed by means of the new ear tests devised by Bárány and his associates. The ear tests would always show either abnormal or normal responses; if the responses were abnormal, the tests would help to determine a lesion either within the ear or within the brain. If the responses were normal, one had then narrowed the diag-

nosis down to (1) a cardiovascular disturbance, functional or organic; (2) an ocular disturbance; or (3) an evanescent toxemia, the source of which should be sought.

The Early Diagnosis of Gastric and Duodenal Ulcer.—Dr. SEALE HARRIS of Birmingham, Ala., said that the diagnosis of ulcers of the stomach and duodenum was often delayed for years by the McBurney or button-hole incision for the syndrome of symptoms usually diagnosed as chronic appendicitis. It was almost the rule for chronic ulcer patients to give a history of operation for chronic appendicitis, without relief, or only temporary amelioration of the symptoms for which the operation was performed. With an experience covering thousands of patients who had had their appendices removed, and who later had digestive symptoms, he was convinced that the surgeon was remiss in his duty when he removed an appendix in which there were no demonstrable macroscopic lesions, without extending the incision and exploring the gall-bladder, stomach, pancreas, and kidneys. While in his opinion the serious operation for gastric or duodenal ulcer should in no case be performed until the patient had had a month or six weeks' dietetic and medical treatment, without relief of symptoms, he believed that the person of cancer age should have the benefit of an early exploration of the abdomen, if medical treatment failed to give complete relief in a few days. He also believed that if there was a recurrence of symptoms, even after months of euphoria following the rest and a modified Lenharz or Sippy treatment, an exploratory operation should be performed. In many such cases the ulcer would have been found to be healed, but there was a recurring appendicitis or there were gallstones or gall-bladder, pancreatic, or even pelvic conditions that were associated with the ulcer. It was not possible in every case to diagnose ulcer without an operation, though in the large majority of cases an accurate diagnosis could be made without resorting to surgery. In a large number of cases in which he had advised operation for the relief of ulcer of the stomach he could recall only two in which the ulcer was not found to be present.

Chronic Myocarditis and Its Management.—Dr. HENRY A. CHRISTIAN of Boston, Mass., said that the guiding signs for the treatment of chronic myocarditis lay mainly in the effects on symptoms and on edema, pulse, and respiration. Little change, except slowing in rate, would be noted in the heart. Physical examination of the heart was the least important thing in guiding the treatment of a cardiac case. A course of treatment should not be ended until the patient was free from edema in his legs, over the sacrum, and at the bases of his lungs. Until then he needed the judicious mingling of rest and digitalis. Often it was advisable to prolong digitalis treatment for many weeks by continuing small doses after a definite digitalis effect had been obtained from larger doses. He knew of no condition in which the immediate results of treatment were more satisfactory than in chronic myocarditis. Eventually the heart would give out, for it was a progressing disease whose advance one knew not how to stop. Relapses were inevitable; how one managed the patient would have much to do with the frequency of relapses; how one treated the patient in the relapses would have much effect on their severity and greatly influence the comfort of the patient. On both depended the lease of life and comfortable efficiency of the patient.

A Consideration of the Clinical Features of Epidemic Encephalitis.—Dr. LEWIS M. GAINES of Atlanta said that epidemic encephalitis was a new disease profoundly affecting the nervous system. It had been prevalent in all parts of the United States for at least two years, occurring in both urban and rural communities, affecting both sexes and all ages. The disease was probably a general infection, with its principal localization in the central nervous system, and most frequently in the periaqueductal region of the midbrain. However, no part of the nervous system appeared immune. On account of the variety of localization, the symptoms were unusually varied and complex, but certain general symptoms were comparatively constant. Epidemic encephalitis should be suspected if two or more of the general symptoms of the disease were present. These symptoms were a state of somnolence or lethargy, marked

asthenia, fever of irregular type, and cranial nerve palsies. If, in addition, the spinal fluid showed a lymphocytosis with an increase of globulins this might be regarded as confirmatory evidence. In many atypical cases the diagnosis was difficult, and might be only a surmise. Treatment was empirical and symptomatic. Spinal drainage had appeared of distinct value. Arspenamin had appeared to benefit some cases in the absence of any indication of syphilis. The mortality of the disease had shown wide variation in the reports of different observers. There were no deaths in the six cases herewith reported. Hall had no deaths among his 16 cases. Abrahamson reported the mortality of 10 per cent., while others reported a mortality rate of 40 per cent. or higher. Mix concluded that the cases which had occurred in the United States had, on the whole, appeared to be milder than those which had occurred abroad. Among recovered cases a certain proportion were left with residual defects.

Ununited Fractures.—Dr. ALONZO MYERS of Charlotte, N. C., said that in the treatment of fractures following injury the question arose as to whether it was better to attempt to restore extremely traumatized parts in normal position, or to allow the inflammation to subside. Jones was emphatic in insisting on securing return of parts as soon as possible to normal position. If this was not done patients presented extraordinary difficulties later on. One never could hope for good operative position later on. The problem, then, was whether drainage first, or secure normal position, or both together. A standardized method treatment was best in which the bones were brought into line and held there, and function of the surrounding joints and nutrition of the muscles and soft parts were maintained. Such procedures tended to limit the number of delayed nonunions.

Treatment of Fractures and Dislocations.—Dr. F. G. HODGSON of Atlanta stated that continuing to use the fracture of the femur as an example, the muscles of the thigh and leg and the circulation of the entire limb could be kept in much better condition by judicious use of massage and electrical stimulation. The patient could be taught to move his patella up and down by voluntary muscular contraction and while in no way disturbing the fracture, keep the thigh muscles in good condition. In the same way he could move the muscles of the leg and foot and prevent atrophy and stiffness in the ankle and foot. After three weeks, careful movements of the knee joint might be begun by the surgeon himself. This should never be delegated to anyone else. When a case so treated was ready to get up and walk, his leg would not show the atrophy, the stiff joints, the contracted tendo-Achillis, and swollen, stiff toes so often observed after the customary treatment. Often some special form of apparatus might be required to maintain a fracture in the best position. Anyone would admit that the orthopedist was the best one to look after these cases. In the after care of some fractures, e.g. Pott's fracture of the ankle, a brace should be worn to prevent the development of deformity after the fracture had healed. Also cases of fractured femurs might be allowed to walk sooner if a brace was used. So it seemed to him that he had reached a stage in the progress of the treatment of fractures and dislocations, when the most satisfactory results might be obtained by putting these cases, from the very beginning, in the care of competent orthopedic surgeons.

Nonunion of the Humerus; Repair by Means of the Bone Graft.—Dr. M. S. HENDERSON of Rochester, Minn., drew the following conclusions: The massive graft had been more successful clinically than either the inlay graft or Albee or the intramedullary graft of Murphy. The rapidity of the establishment of solidity with the massive graft had led him to believe that perhaps Ollier's theory, that the graft might maintain the vitality and function, was correct. Contrary, however, to Ollier's theory, he believed, this was not due to the periosteal layer, but to the firm contact of the endosteal layer of the graft with the endosteal layer of the bone to which it was transplanted. A body cast with a trough for the arm supplied a few days before operation provided the best postoperative fixation that he had been able to provide. A splint should be worn during the period of convalescence after the removal of the

cast. The time at which this could be substituted for the cast differed in each case and should be decided on clinical evidence and roentgen ray examination.

Ligation of the Superior Thyroids in Patients with Exaggerated Toxic Symptoms.—Dr. EDWARD G. JONES of Atlanta said that the plan of ligating a part of the thyroid pole with the vessels was somewhat more popular than any other plan. Probably as good results followed ligation outside the pole. It was apparently not necessary to use nonabsorbable ligature material nor to sever the tissue between ligatures. A completely satisfactory explanation of the remarkable improvement was lacking. Certain patients were too good for ligation and too bad for bilateral thyroidectomy. They should have the resection done in two stages, one side at a time.

The Incidence of Kidney Infection in Acute Appendicitis.—Dr. R. M. HARBIN of Rome, Ga., drew the following conclusions: (1) While mechanical conditions of the appendix may be at times a causative factor, these observations warrant the belief that there are metastatic infections of the appendix and kidneys that seem to have a selective action and point to the existence of some common focus. (2) A greater danger lies in assuming that the actual symptoms of appendicitis are of kidney origin, and in suspicious cases extreme caution should be practiced before excluding the diagnosis of appendicitis in the presence of evidence of renal pathology. (3) The characteristic first day's clinical data with an increasing leucocytosis with moderate temperature would tend to prove the existence of an acute appendicitis in the presence of albumin, blood, and casts in the urine. In order to avoid contamination, it is important that specimens of urine should be obtained by catheter. (4) In the absence of violent symptoms of appendicitis, there may be cases of doubt in which it is prudent to deliberate for twelve to twenty-four hours for additional leucocyte readings, which are usually progressively higher in appendicitis.

Appendicitis in Children.—Dr. ROY ROBERTSON of Durham, N. C., drew the following conclusions: (1) In children the symptoms of appendicitis often are scanty, irregular, and misleading. (2) Appendicitis is more frequent in children than is generally believed, and is more severe. (3) All abdominal pain in children should be looked upon with suspicion, and the physician should be careful about administering purgatives as a routine before the diagnosis is established. (4) All such cases coming under observation should first have a thorough history taken, thorough physical examination made, and all necessary laboratory examinations resorted to. (5) The prognosis is very favorable if the diagnosis is made early and the operation is done early, but after the first twenty-four hours the prognosis is more serious.

The Kondoleon Operation for Elephantiasis; a Report of the End Results.—Dr. W. E. SISTRUNK of Rochester, Minn., said that in the Kondoleon operation we had at our disposal a measure which seemed to control definitely the progress of elephantiasis. The best results were obtained in patients treated by two or three weeks' rest in bed, with elevation and firm bandaging of the limb preliminary to operation. When operating it was necessary to bear in mind the fact that a large amount of skin, subcutaneous fat, and aponeurosis must be removed in order to obtain the best result. It was necessary that the limb be bandaged, when the patients were up and about, for an indefinite period, and oftentimes permanently, following the operation. Before operating a definite understanding should be made with patients regarding the fact that the operation was to be done for the purpose of controlling a disease which, if left alone, usually grew progressively worse; that a perfectly normal limb was not to be expected as a result of the operation, and that it would be necessary for bandages to be worn following the operation. Second, operations in which portions of hypertrophied skin were removed might be done upon patients in whom considerable deformity still resulted after the first operation, with expectation of further improvement.

Impressions Derived from 130 Neurosurgical Cases Studied During Twelve Consecutive Months.—Dr. CHARLES E. DOWMAN of Atlanta drew the following conclusions: (1) Patients referred for neurosurgical operations present such a variety of neurological mani-

festations as to make it necessary for the neurosurgeon to be thoroughly trained in neurology. (2) The chances of relief are often sacrificed by the tardy recognition of intracranial disorders. (3) Chronic headache, vomiting, or disturbance of vision should suggest immediately the possibility of an intracranial lesion. (4) In the absence of these symptoms of increased intracranial pressure there are often so-called focal symptoms which indicate grave brain disease. (5) Prolonged antisyphilitic treatment in the absence of positive evidence of syphilis is unwarranted and dangerous. (6) Where choked discs are present an operation for the relief of increased intracranial pressure should be performed immediately, even though an exact diagnosis has not been made, as delay will often sacrifice the patient's eyesight. (7) Decompression should be performed in cases of brain syphilis with choked disc before antisyphilitic treatment is instituted. (8) Preliminary irritation of the meninges and choroid plexus, followed by arsphenamin intravenously causes rapid improvement both clinically and serologically in many cases of neurosyphilis, and seems to be a method of distinct value in the treatment of such conditions. (9) The use of local anesthesia in operations of a neurological nature has, in properly selected cases, many advantages over the use of general anesthesia.

Acute Diffuse Septic Peritonitis.—Dr. A. L. BLESCH of Oklahoma City drew the following conclusions: (1) The cause of peritonitis of the septic type is most often due to a leak somewhere in the plumbing system of the body. (2) Absorption of toxins and endotoxins is facilitated by upward extension, peristalsis, and diaphragmatic action. (3) Since absorption is facilitated by the factors mentioned above, all of said factors should be minimized to the utmost first by positioning the patient always upon the first suspicion of intra-abdominal inflammation, while waiting for a diagnosis. As soon as the diagnosis is made operation should be planned, peristalsis controlled, and diaphragmatic action limited. (4) It is imperative to withhold purgatives in all cases suspicious of intraabdominal inflammation from the very beginning. (5) The treatment is surgical, and must be clean and incisive. So-called thorough work, which is time consuming, is to be avoided. It consists in simple drainage without fumbling and mauling of the tissues.

Static Difficulties of the Lower Extremities as Influenced by Circulatory Disturbances.—Dr. THOMAS MADDEN FOLEY of Washington, D. C., drew the following conclusions: (1) Clinical evidence shows that many unrelieved orthopedic conditions are due to circulatory disturbances, and may be relieved by proper treatment. (2) A close study of cases to follow up results of treatment will often disclose complicating circulatory conditions which may cause pain. (3) Deep varices in vena comites and atypical angioneurotic diseases of the lower limb are more frequent than are usually thought. (4) Appropriate systemic treatment for central circulatory disturbances must not be neglected.

Seminal Vesiculitis; a Study of 1000 Cases.—Drs. EDWARD WILLIAM WHITE and R. B. H. GRADWOHL of Chicago presented this paper, in which they affirmed that in order of comparative frequency their cases had been attacked surgically, first, for the relief of pain; second, for the evacuation of pus vesicles, and, third, for the removal of hard, indurated fibrous vesicles of long duration which were productive of much discomfort. In their opinion no undue haste need be exercised in advising operations until all palliative measures had been thoroughly exhausted. They had had cases under observation for years characterized by recurrent attacks of acute exacerbation, which were finally cured by persistent efforts at palliative measures. Contrary, however, to the foregoing, many cases of long standing failed utterly to obtain any material benefit by conservative methods, but were absolutely cured following operation. Vesiculectomy was certainly the operation of choice in the hard sclerotic vesicles; whereas, vesiculectomy and drainage had been entirely satisfactory in pus cases and acute catarrhal forms. It had been found that the following classes of cases were all surgical possibilities: (1) Acute catarrhal cases with marked general and urinary symptoms. (2) Chronic fibrous, sclerotic cases, unrelieved by treatment. (3)

Pus and blood after massage, or with ejaculation. (4) Vesical cases causing any obstruction to the higher urinary tract.

Ureteral Calculi.—Drs. A. J. CROWELL and RAYMOND THOMPSON of Charlotte, N. C., drew the following conclusions: (1) Practically all recently impacted ureteral calculi can be removed under local ureteral anesthesia by cystoscopic methods with less fatalities and less injury to the kidney function than that obtained following surgical operative procedures. (2) The success of the method depends upon complete ureteral anesthesia and dilatation, the skill of the operator and persistence in his manipulations. (3) An effort should first be made to remove the stone by this method, since no harm is done the patient by it, and surgery can be resorted to at any time necessary. (4) If crowned with success the fatalities are far less, much time and suffering saved, and a return of the condition less liable.

Ureteral Stricture in the Male.—Dr. ALBERT E. GOLDSTEIN of Baltimore read this paper, of which the following were the conclusions: (1) Nontuberculous acquired ureteral strictures in the male are more than an entity. (2) The ureterogram and pyelogram will demonstrate the lesion. (3) A diagnosis is made principally from the history, the ureteropyelogram and wax bulb hang. (4) The etiological factor concerned is some focal infection, usually the teeth or tonsils, and rarely a Neisserian infection. (5) Accurate technique will assist in differentiating other suspicious lesions.

Kidney Tuberculosis.—Dr. CHARLES E. BARNETT of Fort Wayne, Indiana, read a communication with the following conclusions: (1) Nonoperative cases should include all cases diagnosed or suspected as having tuberculosis who improve following tuberculin, hygienic, and correctional metabolic kidney functional treatment. (2) All abscessed kidneys, whether tuberculous or nontuberculous, should be removed surgically. (3) The glomerulus, with its stasis blood pool on account of its smaller venous outflow than the arterial intake, with an all time two million chances for bacterial lodgement, would seem to make it the most likely portal of entrance. If that be true a cortical invasion should heal the quicker on account of a profuse blood supply. (4) Kidney drainage perfection, with the exception of Henle's loop, is much like a tree. The sap always drains toward the body (pyramids), and finally into the roots (papillary ducts). (5) Agglutinations of the glomerular and convoluted tubules might short-circuit the infective drainage down the distal tubules into the medullopapillary zone, thus accounting for the major habitat of found tuberculous foci. (6) The nonoperative curability of kidney tuberculosis, without a mixed infection present, appears rational and possible. Proof positive is hard to give, but it will finally come through the results of case recoveries from non-operative treatment.

Factors That Lower the Mortality Rate of Suprapubic Prostatectomy.—Dr. GEORGE R. LIVERMORE of Memphis stated that the two-step operation should be performed in every case because: (1) The bladder would be cleaner than when drained through a retention catheter, thus diminishing the possibility of sepsis. (2) The kidneys were better prepared to stand the removal of the prostate as the back pressure was entirely relieved and was prevented from recurring as the drainage was continuous. (3) The bladder was at rest and had become accustomed to the suprapubic tube. (4) The congestion of the prostate had been relieved, thus diminishing the hemorrhage and making its control easier. (5) Through the suprapubic wound there was a certain amount of absorption of toxins, and hence by the antibodies thus produced the patient was rendered less susceptible to infection.

Hemorrhage from the Kidney.—Dr. H. A. FOWLER of Washington, D. C., said that the treatment of these cases was directed primarily toward the control of the hemorrhage. The experience of the past few years had added little that was new. The nature of the treatment to be employed in any given case depended naturally upon the character and amount of hemorrhage. In general where the hemorrhage had not continued over a long period, where the patient's general condition was good, and the demand for immediate control of bleeding was not urgent, conservative meas-

ures should be given a thorough trial before resorting to radical surgical intervention. Bleeding ceased at times after simple ureteral catheterization. Numerous cases of this kind were reported. He had observed this result in a number of instances. Considering the underlying pathology one should expect the result of such simple treatment as the irritation from ureteral catheterization to be only temporary. In his experience the bleeding usually recurred. Injection of the pelvis was often followed by cessation of bleeding. He had used various solutions, such as argyrol, collargol, adrenalin, horse serum, and silver nitrate. His best results were obtained by silver nitrate in 1 per cent. strength. He had employed the intramuscular injections of horse serum with varying results. If conservative measures failed to stop bleeding, and the patient's condition justified it, nephrotomy or decapsulation might be done, provided the kidney on exposure revealed no gross pathology. Equally good results appeared to have been obtained by both of these operations. In cases of severe uncontrollable hemorrhage where bleeding must be properly controlled, nephrectomy was the only operation to be considered.

Transplantation of Cartilage.—Dr. W. T. COUGHLIN of St. Louis stated that for transplantation into the skull in cranioplasty one should be certain to have the transplanted portion thick enough. A thin piece could not afford very much protection. He removed the whole thickness of a costal cartilage as long as was necessary, and then he split it in coronal plane into two halves. He never tried to remove the perichondrium, but always tried to remove the cartilage with its perichondrium intact. This was not because he feared that the graft would not grow without its perichondrium, but because when split the piece curved with its perichondral surface concave. It did this better when the perichondrium was attached. This curving was often of advantage, always so in cranioplasty, for then the concave surface was placed toward the brain and so the cartilage conformed more to the contour of the skull. There had never been any accident in getting the cartilage—neither bleeding, nor opening of the pleura, suppuration, nor lung or chest complications. The patient was never obliged to stay in bed because of the chest wound. In fact, in all the cases in which he had obtained it for purpose other than cranioplasty, the patient was not confined to bed at all. When cartilage was used for cranioplasty it was to be remembered that the cartilage rested on the outer aspect of the skull. The periosteum was reflected back for half an inch all around the margin and pieces were beveled at the expense on their outer surfaces and fastened to the periosteum with catgut. The periosteal flap was thus sutured on to the outer aspect of the cartilage. It had been said that the cartilage united with the bone as it did in life. He had not seen this occur, but he had found elsewhere the cartilage firmly adherent through fibrous tissue. He had never known a piece of cartilage to slip from its moorings or to fracture. He had never drained after a transplantation, but he always established as nearly perfect hemostasis as he could, and only the minimal amount of ligature and suture material and that, always quickly absorbable, was buried in the wound. Around the mouth, nose, and eyes, suppuration was very hard to avoid, and in using free bone grafts aseptic healing was almost imperative with free cartilage. However, his experience was in accord with that of many others. Even though the wound suppurated, free pieces of cartilage, often surprisingly large, healed in the course of five to eight weeks if good drainage was maintained. He had not used it to take the place of loss of an entire segment of the lower jaw. Mostert at first claimed success with cartilage in overcoming such defects. He later, however, was not overenthusiastic for it, but almost everywhere else about the head he had used it always with the greatest satisfaction.

Postoperative Thrombophlebitis.—Dr. FRANK K. BOLAND of Atlanta stated that the treatment of thrombophlebitis consisted in rest, elevation of the part, and the application of cold during the acute stage, and heat afterwards. Opium was often necessary to relieve pain, although he found that the administration of such drugs as aspirin in 5 grain doses every four hours, not only seemed sufficient to give the patient

comfort, but also lowered the temperature, caused profuse diaphoresis, and apparently shortened the course of the disease. It was well for nurses to know that postoperative pain in the legs should not be subjected to massage until the cause of the pain was known. Such well intended, but misdirected treatment, might produce pulmonary embolism. As Binnie said of ventral hernia, the best treatment of postoperative phlebitis was not to have it. While it had been shown that the complication would occur in spite of irreproachable surgery, a consideration of its etiology must suggest that the incidence of the disease might be reduced by closer attention to the details of the operation, which meant sharp, clean dissections, the gentler handling of tissues, and always striving for an improved aseptic technic.

The Combined Examination of the Urinary Tract by the Urologist and the Roentgenologist.—Drs. HOWARD E. ASHBURY and ALBERT E. GOLDSTEIN of Baltimore drew the following conclusions: (1) By the combined method of examination our results show only 1.6 per cent. of failures. (2) Urological lesions were demonstrated frequently by aid of the x-ray where they were doubtful in the two examinations individually. (3) In over 50 per cent. of the cases in which the plain x-ray was negative pathological conditions were found by the combined method of examination. (4) The plain x-ray findings should in all cases be verified by the urologist before a conclusive diagnosis is given. (5) The combined method is the ideal procedure in the diagnosis of urological conditions.

(To be continued.)

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Seventieth Annual Session, Held at Pittsburgh, October 4, 5, 6 and 7, 1920.

(Concluded from page 33.)

Concerning Acute Traumatic Surgery of the Abdomen.

—Dr. LEVI J. HAMMOND of Philadelphia read this, saying that every injury to the abdomen, however slight it might appear at the time, should be considered and treated as if known to be grave, for death might ensue from apparently slight blows. About 10 per cent. of the serious injuries affecting the body involved the abdominal viscera. A blow which did not produce a visible injury to the abdominal wall might contuse or rupture organs within. The immediate and serious effect of these concealed injuries was hemorrhage and rupture of hollow viscera with infection. Shock also occurred. Median laparotomy was the only certain means of ascertaining the extent of the injury and source of hemorrhage. In punctured wounds of the abdomen the seriousness depended upon the degree of injury to the viscera. Early operation was the safest to follow, even though the abdomen might at times be needlessly opened. Leucocytosis in hemorrhage was not, as claimed by some, a reliable factor.

Dr. JOHN O. BOWER of Wyncote, Pa., said that he agreed with Dr. Hammond that every abdominal injury should be considered a surgical case potentially. He had had a different experience with the leucocyte count in practical diagnosis. In every case that had come into the Samaritan Hospital in the past 10 years a leucocyte count had been made. In every instance the degree of hemorrhage had been commensurate with the amount of leucocytosis. There was only one case in which a leucocytosis was found in which operation was not done and that was in a ruptured spleen. The patient was treated expectantly for 48 hours. At the end of that time he was given a bottle of citrate by mistake and within an hour his abdomen was filled with blood. In a rupture of hollow viscera in the abdomen they did not depend upon the leucocyte count because that would cause delay.

Dr. SAMUEL D. SHILL of Chambersburg said that injuries of the abdomen produced conditions that were harder to diagnose than almost any other condition in surgery, and among the injuries the penetrating wounds were the ones that required most attention because there was apt to be perforation of almost any part

of the viscera. In treating penetrating wounds of the abdomen an operation should be done immediately if the patient could be got into the hospital at once. Blows and contusions of the abdomen could be studied a little while longer than the penetrating wounds.

Dr. WILLIAM L. ESTES of South Bethlehem said that these cases of injuries to the abdomen interested him very much, and he had seen a great many of them, usually in industrial establishments. He wished to emphasize the importance of making early determinations by opening the abdomen at an early stage. There was no doubt what ought to be done in a penetrating wound of the abdomen if below the epigastrium, whether from gunshot or entrance of a pole there was always more or less injury to the contents of the abdomen. There would be hemorrhage and frequently very large perforations of the viscera. He had found in the observation of a large series of cases that leucocytosis varied very much. He had made it a rule, and there was a large series, to have a leucocyte count made almost immediately, and where there was a good deal of hemorrhage there was a relative diminution of the red corpuscles and increase of the white. In some cases there is an almost immediate increase in the leucocytosis, but it varied so much that he had learned almost to entirely disregard it. He would counsel everyone who had to deal with these injuries to watch carefully for persistent stasis of the intestines and if there was vomiting and persistent distention of the abdomen and signs of shock he would always advise that the abdomen be opened at once.

Dr. HUGH E. MCGUIRE of Pittsburgh wished to say a word in regard to morphine in abdominal injuries. He had a rule in the hospital that no man was to receive morphine until they knew what was wrong with him. If there was a small area of contusion and the temperature went to 100°, the abdomen was opened. If one waited until vomiting and all the symptoms of ruptured bowel set in nine-tenths of the cases were going to die. One could open the abdomen and obtain information. He would rather open a case and be mistaken than have the man die. He made it a rule to open these cases in the first six hours, if possible.

Dr. JOHN P. GRIFFITH of Pittsburgh said that this paper was a very important one, particularly for men who saw considerable of these cases. They taught their interns and medical students, even in a case of fractured clavicle, to always examine the abdomen. Almost invariably there was one sign of peritoneal trauma, that was the greatly reduced peristaltic action. In a rupture of any of the viscera, even if there is not much escape of contents, very shortly after the injury there would be almost a complete cessation of peristalsis. The next valuable point in the diagnosis was the tenderness at or near the site of trauma. In his surgical work one sign elicited properly had helped him in more cases than any other thing. A hemorrhage that will diffuse over the peritoneal cavity might not produce much shock, but it would produce a cessation of peristalsis within 5 or 6 hours of the trauma.

Dr. RICHARD J. BEHAN of Pittsburgh said that one factor in traumatism of the abdomen was cessation of abdominal respiration. He had examined many cases of abdominal injuries and that was one of the first things that was absent. It came on as quickly as did the rigidity of the abdominal muscles.

Early Diagnosis of Perforated Gastric and Duodenal Ulcer.—Dr. WILLIAM L. ESTES, JR., of South Bethlehem read this paper, saying that early diagnosis of perforation of a gastric or duodenal ulcer could be made in the vast majority of instances by the severe, sudden pain of onset, history of previous indigestion, boardlike abdominal rigidity, and marked retraction of the upper abdomen sufficient to cause a transverse line just above the level of the umbilicus. In atypical cases radiogram of the abdomen for the detection of gas along the diaphragmatic line and a shifting tympany over the liver in the lower axilla might serve to identify a perforated digestive ulcer.

Technique of Gastroenterostomy.—Dr. HAROLD L. FOSS of Danville, Pa., read this paper, saying that gastroenterostomy, though one of the most valuable of operations and, in point of results, the most satisfactory treatment for duodenal ulcer, yet occasionally was followed by disappointment often due to faulty

technique or mechanical defect in the operation. Among the commoner untoward results were vicious circle, gastrojejunal ulcer, reactivation of the original ulcer, the production of new ulcer and malignant degeneration in a gastric ulcer already established. Of the mechanical defects the commonest were to be found in the use of the Murphy button, bobbin, or similar devices; the formation of a long jejunal loop; the Roux or Y technique; such complex procedures as that of Ehrlich or Vulliet; use of the anterior operation; failure to properly locate the stoma; failure to make an opening of sufficient size; the use of nonabsorbable suture; failure to properly funnel the stomach through the transverse mesocolon; infection during the operation with formation of adhesions; the performance of gastroileostomy; failure to combine with surgical careful postoperative medical treatment; operation without sufficient lesion or lack of thoroughness at operation such as removal of remote sources of infection.

Dr. CHARLES H. FRAZIER of Philadelphia said that a point which ought to be emphasized and was not at many surgical clinics was regulation as to the care of the patient after the operation. So little was known about ulcer that one could not be very exact in prescribing medicines or diets for the post operative period. At the same time it seemed to him that common sense dictated that a patient who had had an ulcer and a gastroenterostomy could after a considerable period resort to a diet which the person was accustomed to who had a perfectly normal stomach, and where food passed through the natural outlet. We were justified in recommending the administration of alkalies repeatedly throughout the day and it was to the patient's advantage for a considerable period after the operation had been performed to restrain his diet in regard to quantity and resort as far as possible to frequent feedings—light breakfast, something between breakfast and lunch, something between lunch and dinner, and then perhaps a little when the patient went to bed. In other words, he should have, instead of three feedings, six, and the use of alkalies before each feeding and perhaps in the interval between.

Dr. ROBERT T. MILLER of Pittsburgh said that the paper of Dr. Estes seemed to him particularly timely. These cases about which he spoke, practically all of them, did without treatment. Mayo Robson estimated that of those patients who came to operation twelve hours after perforation one-third died within twenty-four hours, and of those who came after forty-eight hours practically 100 per cent. died. It was obvious that early diagnosis was essential. The only criticism he would make of Dr. Estes's paper was that it had been read in the wrong section. The difficulty was not with the surgeon, the difficulty lay with the man who first saw the case, who temporized, used a little morphia, a hot water bag, letting the family down easy. The surgeon operated as soon as he saw it. He must have the case early if he was to do very much good. His paper served in particular to emphasize the thing that was essential, namely, to go after the early diagnosis in the hands of the man who saw the case and not to think of this thing as a surgical problem. It was a problem in internal medicine primarily.

Dr. DONALD GUTHRIE of Sayre said that there was one point in Dr. Estes's paper he would like to mention: that was, he spoke of the early history as being a factor in the diagnosis of perforation of acute ulcer. He had noticed several times in his work that he had what he believed were acute and septic ulcers, not old chronic ulcers which had perforated, but acute septic ulcers which had perforated without any previous history of indigestion. He had not taken the patient's word that they had never had stomach trouble previously because it was hard to get a history from one so acutely ill as these cases, but he had gone to the families of these patients and tried to get a history of former stomach trouble. He had had six cases of this in his experience. He spoke of it for the reason that one should not rely upon the history of chronic indurated ulcer in order to increase his assurance that the case under consideration was a perforated duodenal ulcer. He thought Dr. Frazier had led us on the right track. It seemed to him that there was no class of cases where the surgeon should cooperate with the internist more than in these cases. Perhaps the jejunal ulcer might be prevented

by giving these patients large, frequent and heavy doses of alkalis immediately after operation, continuing these alkalis and being sure that the diet be regulated under the direction of a live, well-informed medical man and that the alkalis be continued for many months following the operation.

Dr. J. STEWART RODMAN of Philadelphia said that he recalled one case in which there had been entire absence of shock and that had been the only one in the series. It was a soldier who had walked to his tent two hours after perforation, his pain had continued and he came to the hospital three hours after he had perforated. He had made a good recovery. The rest presented rather severe shock. One case in which the shock had been so severe when the patient reached the hospital it was impossible to do anything. The patient was in *extremis* and died an hour and a half to two hours after admission to the hospital. Whenever there was perforation of a hollow viscus we would invariably get a loss of peristalsis and that was the almost infallible diagnostic sign, coupled with other symptoms which we would get in these cases. He agreed heartily with Dr. Guthrie. As far as one could lay down a rule he believed it was better not to do a gastroenterostomy in these cases. As far as Dr. Foss's paper was concerned he believed there was a good deal being said about the failure of gastroenterostomy and it was interesting to hear Dr. Foss recount his experience because he has had considerable experience in abdominal surgery. Gastroenterostomy had been first proposed as a palliative procedure and it had remained that for gastric ulcer up until the present time and always would. It was a curative procedure so far as duodenal ulcer was concerned, but unless it was combined with destruction of the ulcer in gastric ulcer it was certainly nothing but a palliative procedure.

Dr. W. WAYNE BABCOCK of Philadelphia said that when a gastroenterostomy was done it cured about 85 per cent. of duodenal ulcers. When the ulcer was in the stomach and up along the lesser curvature, the percentage of cures by gastroenterostomy dropped very low. The normal antidote to the acid chyme was the bile. Owing to this fact, about a year ago he had stopped doing gastroenterostomy for ulcer and took the gallbladder and planted it into the ulcer bearing area. If the ulcer were in the stomach the ulcer was excised and the gallbladder implanted in the orifice that was left. This gave a normal alkali which was supplied by the body for the rest of the patient's life. In several x-ray studies there was found no food or bismuth regurgitating into this gallbladder. In some 200 cases the evidence during the first two years had been that secondary complications were rare and the patients lived very comfortably with the bile running into the stomach. The patients got rapid improvement and got along just as well as they did after gastroenterostomy.

Dr. MOSES BEHREND of Philadelphia said that it had been his custom to do gastroenterostomy in every case of perforation. Recently he had tried the operative procedure of not doing a gastroenterostomy. The results were just as good, but time was still too short to compare these cases in which he did a gastroenterostomy and those in which he did not do it. It seemed whatever method was used, if one had a proper technic, that cases will get well. He did not believe that a non-absorbable material was responsible for the gastrojejunal ulcer.

Dr. EMORY G. ALEXANDER of Philadelphia said that in the Episcopal Hospital they were most fortunate and had had some 50 cases of perforation of duodenal ulcer in the last 10 years and had found in the great majority of these cases they gave a distinct history of stomach trouble. Frequently if one questioned the patient at the time of the first examination he was generally suffering and was unable to collect himself sufficiently to give you accurate data on that subject, but if you would visit him some days after the operation and question closely, you would find out. He would say "Oh, yes, I have had stomach trouble," and probably he would say he had had it for years. The symptom to lay stress on was the sudden onset and rigidity of the right rectus; absence of liver dullness he had always thought of some value. The majority of surgeons, however, did not believe that to be of any marked

value because one did not know the normal liver dullness for that patient.

Postoperative Complications and Sequelæ of the Respiratory Tract.—Dr. H. RYERSON DECKER of Pittsburgh read this paper saying that on the average one person in every 45 operated upon developed a respiratory tract complication and one case in every 200 died from such complication. Pneumonia was by far the commonest complication, chiefly the croupous type. There had been in their series of 5976 cases 10 of pleurisy and 7 cases of bronchitis, 2 cases of embolism of the pulmonary artery had been observed. Latent tuberculosis might be lighted up or an active lesion aggravated by operation, especially if inhalation anesthesia was used. Exposure of the patient before and after operation to unaccustomed conditions was an important predisposing cause of respiratory trouble, likewise various infections pre-existing in the body.

The Problems of Modern Chest Surgery as Met by Physiological Drainage.—Dr. LEVER F. STEWART of Clearfield, Pa., read this paper saying that the dictum in surgery was to drain in the presence of infection and in lung surgery to keep the pleural cavity drained and free from air. This was made possible by the use of the one-way valve used in the Army box gas mask which met the physiological requirements. This had been first suggested to him by Yates in 1918. He had attached this valve to the Brewer tube, modified its application so as to continue indefinitely the protection of the pleura from the air and at the same time permit the use of Dakin's solution. To the distal end of the tube the gas mask was attached. The outer flange of the tube was placed under the skin which was sutured over it with catgut.

Dr. FREDERICK B. UTLEY of Pittsburgh said that it was common for a man on the medical service to transfer a man to the surgeon for operation and he said, "Oh, very well, I shall operate on the patient to-morrow morning," then he thought no more about the patient until he appeared in the operating room, having had no examination as to the ability of the patient to take an anesthetic or what would be the best anesthetic. It was of more importance at the time to determine whether the patient could take an anesthetic from the standpoint of the respiratory tract than to take the measure of the circulatory system. It would seem to him wise to have all patients in the hospital a few days if possible before operation. He had seen two or three chests this spring in which Dr. Stewart's method had been used and it had been amazing to see how completely the pleural cavity had filled with the expanding lung.

Dr. A. RALSTON WELLS of Philadelphia said that the prime thing in Dr. Decker's paper was the importance he placed on the anesthesia used. All inhalation anesthesia, of course, made the lung work to a fuller extent. It would, therefore, cause a passive hyperemia of that lung and would therefore give a better opportunity for culture of any bacterium that happened to be present. The nitrous oxide was the least harmful of all the inhalation anesthetics. He would like to advocate the advantage of a spinal anesthetic which was moderately safe. With spinal anesthesia given by a person who was familiar with its use it appeared to him that would overcome a great many of the difficulties experienced in chest surgery. The drainage tube of Dr. Stewart was very apt and would lessen mortality to a great extent.

Carcinoma of the Breast, with a Study of the Results Obtained in 218 Cases.—Dr. WALTER E. SISTRUNK of Rochester, Minn., read this paper saying that it was based upon the results obtained in 218 consecutive cases in which primary radical amputation of cancer of the breast had been performed from 5 to 8 years previously and who recently had been traced. The recurrences had been found to occur largely in late cases and evidently came because cancerous tissue had been left in regions inaccessible to the knife while the highest percentage of cures and the infrequent recurrences had been found in those operated upon early in the disease before glandular involvement could be demonstrated. The end results were probably better than those in any other types of cancer except the basal called epithelioma of the skin and cancers of the lip. When the public was better educated

as to the necessity of seeking surgical aid early for all breast tumors and when it was generally recognized by the entire medical and surgical profession that the day of watching breast tumors was past it seemed likely that the formation of many cases of malignancy would be prevented and that 75 to 80 per cent. of patients with cancer would obtain 5 to 8 year cures.

Dr. MOSES BEHREND of Philadelphia said that in order to get results it was absolutely essential to clear out all diseased tissue and it was of special importance to clear out the glands that one could feel and see.

Dr. DONALD GUTHRIE of Sayre said that if one would recall Dr. Sistrunk's statistics he would see the great difference between the number of patients who remained well without axillary involvement as compared to the number who had recurrence following axillary involvement. It all meant that the tumors must be gotten to the surgeon earlier. The three-year period, as Dr. Sistrunk had said, was not time sufficient for us to draw any optimistic conclusions; neither was the five-year period. The importance of giving x-ray treatments to these patients after operation he was glad to touch upon. Following the suggestions of Dr. Wainwright of Scranton he had for the past few years been having these x-ray exposures to the field of operation before closing the skin. The x-ray experts told him many of the rays were filtered out by the skin and that a valuable way to attack cancer cells was at the time of operation before the skin flaps were closed.

Dr. WALTER E. SISTRUNK of Rochester, Minn., said that Dr. Behrend brought up the question about the glands in the axilla; he did not think we felt the glands in any but a few of the cases in which they were found to be involved. The glands that were felt were under the scapula; high up in the axilla it was hard to feel them. He was interested in Dr. Guthrie's remark as to x-ray and the preliminary treatment of these cases with x-ray, and he thought that was a good measure and after hearing Dr. Clark's paper here to-day he felt that it would be a very good plan to treat these cases with heavy doses of radium or x-ray before as well as after operation.

Treatment of Complicated Cleft Palate.—Dr. JOHN B. ROBERTS of Philadelphia read this paper, saying that delay in starting the operative treatment of congenital clefts of the oronasal partition beyond the first month or two of life was usually an error of judgment. If the child's condition did not permit completion of the operation, the harelip could be given attention about two weeks after the osteoplastic work had been done. The wire in the maxilla should not be disturbed for 4 or 5 months. In bilateral clefts the protruding intermaxilla was forced back into place but should never be removed. Two or more operations might be needed to entirely close the defect. No routine method of uranoplasty or staphyloplasty could be successfully used. Any residual defects might be corrected in the second or third year.

War Surgery of the Face and Jaws Applied to Injuries in Civil Life.—Dr. ROBERT H. IVY of Philadelphia read this paper, saying that bone grafting in ununited fractures of the mandible with loss of substance was an established procedure. This was especially adapted to cases in which a whole segment of the bone was lost through osteomyelitis or necrosis or those in which a part of the bone had been removed on account of a tumor. Formerly these had been unsatisfactorily treated by prosthetic appliances. The best adapted graft was that obtained from the crest of the ilium. If attachment to bone could be obtained for the graft at only one end, a graft consisting of a part of the rib with its cartilage attached was most suitable because if bone was implanted into soft tissues it underwent rapid absorption.

Dr. A. KALSTON MATHENY of Pittsburgh said that some of these cases had such a hopeless deformity and the operation was so formidable that he had found it feasible in a few cases to close the lip first and not touch the palate. With lateral pressure for 5 minutes 3 or 4 times a day over a period of 8 months to a year a hopeless condition was changed to a very easily operable one. He had seen a cleft of an inch or more reduced in this way to one-eighth of an inch. There was in the market a very useful nipple with an obturator

attachment that rested against the roof of the mouth.

Dr. M. BEHREND of Philadelphia said that it has been his custom to operate upon these cases within the first 48 hours because the babies would lose weight and strength owing to inability to take food properly. He closed the palate first by the Brophy method and closed the lip some weeks later.

Compound Fracture of the Femur.—Dr. DANIEL A. WEBB of Scranton read this paper saying that in 1916 the mortality of thigh wounds in the British army was 80 per cent. In 1917 the Thomas splint was issued to stretcher bearers. Then cases arriving at the Casualty Clearing Station instead of being shocked and moribund were ready for immediate operation. The death rate for thigh wounds dropped to 15 per cent. The end results had greatly improved under the use of the Thomas splint. The teaching of the principles of treatment of fractures and their practical application must be vastly improved if ordinary justice was to be done to fracture cases in the future. A Thomas splint ought to be part of the equipment of every ambulance and internes should be taught its use.

Dr. WILLIAM L. ESTES of South Bethlehem said that before the war we had been accustomed to use the Thomas splint, but we used it without the combination of the Balkan frame and with that properly adjusted it makes almost an ideal dressing for fracture of the femur. While we said it was necessary perhaps to learn from one who had done a great number of fractures, yet each fracture was an individual study. No one who attempted to treat a fracture by the same sort of apparatus, even though it might be as perfect as this, was going to get as good results as the surgeon who studied and adapted his apparatus to the fracture itself, not to the fact that it was a certain kind of fracture of the femur or of the tibia, or that sort. There were things about the Thomas splint which lent themselves to fracture of the femur. Treating of fracture was not simply to get union of bone. It was that, of course, but much more it was getting back of function of the part and getting back a measure of usefulness that would make the man perfectly capable again.

Dr. JOHN H. GALBRAITH of Altoona said that his experience with the Thomas splint has been limited almost entirely to the straight Thomas as used at Liverpool and in line work in France. Even at a big base center they had had no ice tongs. He had seen one pair there which had been applied at another hospital. He heartily agreed that all cases should have the ice tongs applied, except in fractures close to the condyles. It seemed to him the use of the adhesive old-fashioned traction straps would answer just as well. The few cases he had seen where the ice tongs had been used the patient complained bitterly.

Dr. JOHN B. LOWMAN of Johnston said that just as the author had said, the Thomas was the ideal first aid splint. After application of the Thomas splint at the front they did not get these cases in severe shock as they did before. He thought it was an admirable splint to be used in all industries at the present time. They had adopted it and taught the application to their first aid men by moving pictures. If the ice tongs was applied properly there was not so much pain. A good deal of pain was caused by a little exudate under the periosteum.

Dr. JOHN D. V. SINGLEY of Pittsburgh said that he had been very much interested in the method of treatment of fracture of the femur by the method of Pearson's bed and calipers. This interest had been mainly aroused by Dr. Slocum who had had a wide experience with it. He had had a small experience, but sufficient to emphasize several points in connection with it. In the first place the results were immeasurably superior to any other method he had been familiar with previously. Second, it was much more comfortable to the patient. He could not confirm the statements that the calipers were painful. He had seen cases in which the patients complained, but he believed it was probably due to faulty application of the calipers.

Bone Necrosis with Special Reference to Tuberculous Lesion.—Dr. MARVIN W. REED of Bellefonte, Pa., read this paper in which he said that tuberculosis of bone began usually as an infection of the epiphysis and, while it might burrow through the cortex and periosteum,

teum and discharge as an abscess, the usual process was to extend into the joint. Early symptoms might be very indefinite. The treatment was hygienic with active surgical intervention in suitable cases.

Dr. ALEXANDER ARMSTRONG of White Haven said that the thing that struck him first was the infrequency of bone and joint conditions in tuberculous cases. He might say on an average of 300 cases which they had at White Haven he could count only 5 cases of bone or joint tuberculosis. He would refer to the work of Rollier of France, in reference to the sun bath treatment. With free pus the sun bath with x-rays and violet rays would give astonishing results, would give a joint with function. He had a case like that now in which the patient had gone from surgeon to surgeon and they all had simply thrown up their hands and said, "We can do nothing for you except amputate," and after a year's treatment by sun baths he had gotten complete healing.

The Diagnosis and Treatment of Carcinoma of the Rectum.—Dr. DAMON B. PFEIFFER of Philadelphia read this paper saying that carcinoma of the rectum was a common disease ranging next in frequency to carcinoma of the stomach. The mortality of cancer of the rectum unoperated was the same as that of cancer of the stomach, namely, 100 per cent. Yet strenuous efforts were made to diagnosticate and operate upon cancer of the stomach while general apathy existed concerning the disease in the rectum in spite of the fact that chances of cure in the latter were better. Diagnosis was easy but could be made only by examination. The index finger was the only instrument needed. Fully 90 per cent. of rectal cancers were readily palpable with the finger and those higher up could be diagnosed by signs of obstruction. Operation was the only treatment. The prejudice against the permanent colostomy often required was not well founded. Patients get along nicely and for years lead active lives with permanent colostomy.

Dr. J. ELMER PORTER of Pottstown said that an examination of the rectum with the gloved finger or speculum or both should be made in every patient coming with symptoms of rectal disease. This would present in many instances the hopeless condition appearing in the surgeon's office. Another valuable thing was the exploratory median abdominal incision which permitted an examination of the rectum and adjacent organs, also the liver for secondary involvement.

Spontaneous Rupture of the Gallbladder.—Dr. EVAN W. MEREDITH of Pittsburgh read this paper saying that operation was indicated as the reported cases showed the usual time and mortality ratio that obtains in other perforative lesions in the abdomen. The grave condition of many of these patients would limit surgical interference to the minimum and cholecystostomy with free local drainage would be the procedure of choice. Rubber tissue with or without gauze in the form of a cigarette drain would satisfy all the drainage requirements. Suprapubic drainage was seldom necessary.

Repair and Anastomosis of the Bile Passages for the Relief of Chronic Jaundice.—Dr. MOSES BEHREND of Philadelphia read this paper saying that the manner in which most surgeons performed cholecystectomy could not but be fraught with danger to the common duct, injury of which might lead to cholemia. Such injury could be prevented if during operation the structures within the gastrohepatic omentum were exposed to the eye. A careful operation showed that there were 25 per cent. of variations in the relation of the ducts to each other and to the blood vessels. Where the common duct had been destroyed the best procedure was the anastomosis of the hepatic duct to the duodenum or stomach. When jaundice was due to tumors of the pancreas or an irremovable tumor at the papilla of Vater great relief could be given the patient by the anastomosis of the gallbladder or common duct to the stomach or duodenum. Every case of chronic jaundice should be operated upon as quickly as possible. They were usually held too long by the internist.

Dr. JOHN J. GILBRIDE of Philadelphia said that in anastomosing the various ducts of the gall bladder he believed we should retain as far as possible the physiological function and not anastomose the gall bladder to the stomach except under extreme urgent necessity

where one could anastomose the parts to the duodenum. The duodenum was closer and better results would be obtained by anastomosis of the gall bladder or duct directly into the duodenum. That was where the bile belonged and where it performed its function.

Dr. A. RALSTON MATHENY of Pittsburgh said that Dr. Meredith had mentioned the analogy between the acute appendicitis and acute cholecystitis. His cases of perforation were cases of acute cholecystitis. The analogy was well placed because the condition must be handled exactly the same way as in acute appendicitis.

Dr. M. BEHREND of Philadelphia said that attention had been called to the fact that the gallbladder should, if possible, be anastomosed to the duodenum instead of the stomach. Sometimes mechanical difficulties were so great where adhesions had bound down the duodenum that it was safer to anastomose the gallbladder to the stomach instead of the duodenum. It was remarkable how the stomach would tolerate bile. In several of these cases no vomiting occurred after operation where the gallbladder had been anastomosed to the stomach.

The Value of Subtotal Hysterectomy in the Treatment of Fibromyomata of the Uterus.—Dr. F. HURST MAIER of Philadelphia read this paper saying that in determining the respective value of total and subtotal hysterectomy in the treatment of fibromyomata we could ignore the facts that true carcinoma of the cervix was present in at least two per cent. of the cases and that there was a definite percentage of malignant disease associated with cervixes retained after the supravaginal procedure. The personal equation of the operator must be the deciding factor in the choice of operation. For the class of surgeon whose mortality in subtotal hysterectomy was only 2 per cent. this should be the operation of choice as this represented the best percentage of mortality in total hysterectomy. In hands not especially skilled the subtotal operation gave the greatest safety.

Dr. HERBERT B. GIBBY of Wilkes-Barre said that Dr. Maier had opened up a question which was of extreme importance. End results were really what the surgeon was after and the surgeon who had a very high mortality in his operation certainly did not get good end results. He had given us a very fair presentation of the incidence of malignant disease in the services associated with fibroid uteri. The possibilities of radium treatment it seemed were something that was going to prove of great value in the future.

Dr. EDWARD A. WEISS of Pittsburgh said that he had always felt that the cervix had a very distinct function to perform. He always felt that the cervix was to the pelvic contents what a cork was to an inverted bottle. It was a distinct plug for the pelvic contents and its preservation was of decided benefit.

The Practical Aspects of Antenatal Hygiene.—Dr. EDWARD A. SCHUMANN of Philadelphia read this paper in which he said that antenatal hygiene was divisible into three groups: (a) The sociological factors, housing, sanitation, food, and occupation as applied to the pregnant woman, or, better, to the woman in whom pregnancy was a possibility. (b) Eugenics and the care of the woman and her fetus from the standpoint of prevention of infection, recognition and treatment of disease, if present, and those prophylactic measures against toxemia which were so generally understood. (c) The prevention of birth traumatism by careful estimation of the capacity of the maternal passages, the relative size of the pelvis and fetus, and the conduct of labor in such fashion as to secure the best possible results for mother and child. Maternal fever above 104 deg. F. was highly dangerous to fetal life, so special care should be taken in febrile diseases to keep the temperature below this point. The pregnant woman should be seen and carefully examined by her physician early in pregnancy.

Some Practical Aspects of the Care of a Parturient Woman and Her Child.—Dr. EDMUND B. PIPER of Philadelphia read this paper saying that any time during the first two weeks of the puerperium we frequently saw a sudden rise in temperature, even up to 104 deg. F., perhaps with a real chill. Our first thought was sepsis, and should be, but there were many other conditions, such as engorgement of the breast or retained lochia, which may cause it. The lochia might be brought

back to normal by the use of the Fowler position. The intrauterine douche might be used to wash out necrotic material and induce drainage. The final step was examination of the mother six or eight weeks after her delivery, so as to detect any ill effects of the confinement.

Factors in Fetal Mortality.—Dr. WILLIAM H. GLYNN of Pittsburgh read this paper, saying that in obstetrics careful examination of the patient to enable us to make an accurate diagnosis of abnormal conditions was very essential. Fetal mortality in cases of posterior occiput was still very high. If it was recognized early and proper methods applied, many children would be saved. The insistence upon relief of pain in childbirth had brought into use poisonous drugs, especially morphia, which were dangerous to the fetus. The use of pituitary extract was responsible at times for fetal death. The dose should be small and repeated if need be. A toxic state of the pregnant woman was a matter of grave concern as to fetal life. In grave toxemias where the child was viable labor should always be induced.

Ovarian Pregnancy. Report of a Case with a Six Months' Dead Fetus.—Dr. SIDNEY A. CHALFANT of Pittsburgh read this paper saying that the case of ovarian pregnancy reported had been in a woman of 40 who had had two children, the youngest 9 years of age, menstrual history normal. There was a smooth tumor in the midline half way to the umbilicus. On operation a dead fetus was found within the right ovary. The right tube and ovary were removed without difficulty. Recovery was uneventful. This case conformed to the criteria of Spiegelberg.

SECTION ON MEDICINE

Dr. M. HOWARD FUSSELL, PHILADELPHIA, IN THE CHAIR.

Practical Points in Heart Diagnosis.—Dr. S. CALVIN SMITH of Philadelphia read this paper saying that the heart reflected disturbances and alterations in other structures of the body; many heart affections were secondary to infective processes elsewhere in the body; it was not possible in study or in treatment to dissociate the circulatory system from other systems of the body. A clinically satisfactory diagnosis could not be based on instrumental examination alone nor on physical signs alone; such evidence must be correlated with a study of the family history, the personal history, the presenting symptoms, the evidence afforded by the clinical laboratory, and, where possible, with a study of the heart response to exercise.

Errors and Oversight in the Use of the Blood Pressure Apparatus.—Dr. GEORGE E. HEIN of Pittsburgh read this paper saying that factors not necessarily due to pathological changes in anatomy of the cardiovascular system, but those producing changes in the arterial tension were often not sufficiently taken into consideration. Variations in pressure produced by mental reactions or emotion were especially apt to lead to the wrong impression. A vicious circle might be set up in a neurotic patient by the knowledge of changes in his or her arterial tension. A wider limit for normal was necessary for the interpretation of both systolic and diastolic pressure than generally accepted. Each individual set his own standard.

Pericarditis.—Dr. GEORGE E. HOLTZAPFLE of York, Pa., read this paper in which he stated that there were few infectious diseases in which pericarditis might not occur; it might be the only disease discoverable. In every case of rheumatism, tonsillitis, pneumonia, or pleurisy the heart should be examined for pericarditis. In attempting to diagnose pericarditis one must keep in mind other conditions which might occur in the chest wall, the mediastinum, below as well as above the diaphragm. It might be mistaken for a painful condition of the stomach.

Some Suggestions for the Treatment of Hyperthyroidism.—Dr. FREDERICK B. UTLEY of Pittsburgh read this paper saying that the normal function of the thyroid gland was believed to be its control over cell growth, calcium metabolism, katabolism, antitoxic and immune bodies. The continued response of the thyroid gland to abnormal stimulation finally resulted in hyperthyroidism with its various symptoms. An early recog-

nition of any abnormality of the function of the thyroid gland was essential, and all possible etiological factors, nutritional, toxic and psychic should be eliminated as promptly as the patient's condition permits. Surgical procedures should be directed toward the etiological factors and not the gland proper except in those cases where it was expedient to spare the patient at once from the drive of the over-active thyroid when the removal of foci should follow the surgery on the gland. Further treatment consisted of rest in bed with suitable surroundings and diet, and the administration where indicated of the neutral hydrobromide of quinine, calcium chloride, sodium phosphate, intestinal antiseptics and the syrup of the iodide of iron, the latter in small, properly guarded doses.

Dr. LAWRENCE FITCHFIELD of Pittsburgh said that in cases in which symptoms of hyperthyroidism predominated, if the usual treatment by adrenal therapy and x-rays failed to give satisfactory results we must advocate removal of part of the gland. In hyperthyroidism we must feed thyroid gland or its derivatives. X-ray treatment should be well tried before submitting to the surgeon. It had been demonstrated that simple goiter in school children could be prevented and removed by the very moderate use of the iodides.

A Method of Distinguishing from Among Various Microorganisms Present in a Patient Those that Are and Those that Are Not Acted on by that Patient's Whole Blood.—Dr. MYER SOLIS-COHEN and Dr. GEORGE D. HEIST of Philadelphia presented this paper saying that when several microorganisms were present in a culture from a patient's nares, nasopharynx, throat, ear, sputum, urine, or feces, if they were incubated in the whole blood of that patient, some would disappear while others would grow luxuriantly. Varied evidence pointed to the existence in such a patient of a high degree of immunity to those organisms that disappeared from his blood and of susceptibility to those organisms that grew in it. These phenomena had been utilized in preparing autogenous vaccines that contained only those organisms that grew in the patient's blood and did not contain those organisms which the patient's blood already had the power of destroying or inhibiting.

The Effect of the Influenza Epidemic on Tuberculosis. Dr. CHARLES H. MARCY of Pittsburgh read this paper, saying that in this series there have been collected 533 cases the onset of whose symptoms was referred to an attack of influenza. The number of patients known to have had tuberculosis prior to the onset of influenza was comparatively small. In the majority of these cases the influenza had reactivated old quiescent lesions. In 34.3 per cent, of the series studied the onset of tuberculosis dated from the influenza. A large number of cases in the series showed other conditions which were nontuberculous, though they simulated tuberculosis.

Postinfluenza Chest.—Dr. ARTHUR C. MORGAN of Philadelphia read this paper saying that the pathology of the chest following influenzal pneumonia differed from that usually found in the ordinary postpneumonic chest. Because of this confusion, there was a difficulty in diagnosis, and mistakes had been made in the interpretation of physical signs present. Primary location of a tuberculous lesion was in the apex, extending downward by continuity. The usual pneumonia pathology affected the lower lobe or a portion thereof; therefore, delayed resolution, effusion, pleurisy, localized empyema or pericarditis might be manifest in any part of the chest, giving rise to the physical signs described.

Psychotherapy of Tuberculosis.—Dr. HENRY M. NEALE of Upper Lehigh, Pa., read this paper saying that many of the therapeutic measures adopted in treatment of tuberculosis for the past century were therapeutically antagonistic to each other, and yet all had met with a certain degree of success. All therapeutic action was more or less subject to mental conception or expectation. Tuberculosis was more controllable by the mental attitude than any other disease. The mentality of all tuberculous patients must be carefully analyzed before commencing any definite line of treatment. Autosuggestions played a most important part, especially in the treatment of incipient cases. In necessary medical treatment to be instituted, great care and judgment should be used. All measures should be carefully explained. Considerable study was necessary to formu-

late a line of action best adapted to one's own personality, but, after it was once understood and put into practice, often the most surprising results would be obtained.

The Results of Sanatorium Treatment for Tuberculosis.—Dr. H. R. M. LANDIS of Philadelphia read this paper saying that if the tuberculosis sanatoria were confined in their efforts to those for which they were originally intended, that was the care of early cases, the number of individuals progressing into the advanced stages of tuberculosis would be rapidly diminished and in this way the infection of others would be correspondingly reduced. As it was the sanatoria cared chiefly for advanced cases which were apt to relapse after leaving the institution. This led many to conclude that sanatorium treatment was not very effective. If he were to single out the one great advantage which the sanatorium offered he would unhesitatingly say "rest." The greatest disappointment from sanatorium treatment was the tendency of those so treated to relapse; but it must be borne in mind that one of the chief characteristics of tuberculosis was to relapse. Given the type of case which offered a chance of being improved he thought it could be said safely that the well conducted sanatorium did all that had been claimed for it.

Gastric Disease and Relation to the Glands of Internal Secretion.—Dr. TRUMAN G. SCHNABEL of Philadelphia read this paper saying that with dysfunction of the ductless glands there was sometimes found dysfunction and pathology in the stomach. The relationship of the ductless glands to the stomach had some evidence in its favor. Perhaps the internal secretions influence the stomach directly. Organotherapy should be tried in gastric disease especially those of the functional type, for it might be successful in a small number of cases.

The Diagnosis of the Functional Capacity of the Kidneys in the Various Types and Stages of Nephritis.—Dr. ROY R. SNOWDEN of Pittsburgh read this paper saying that the urinary findings in nephritis was no indication of functional capacity of kidneys. Large amounts of albumin, casts and even blood might be present, and yet kidneys excreting all waste products normally. On the other hand, cases in which there was serious retention might show only a trace of albumin and a few casts. Since it must be borne in mind that one must never judge the functional capacity of kidneys on evidences found in the urine alone, diagnosis of the ability of the kidneys must rest on (a) clinical symptoms and (b) functional tests. Functional tests were the best indices of excretory ability, as they revealed early changes which preceded the development of clinical symptoms. Clinical symptoms were also of importance, especially since their significance was now well understood in the light of modern chemical metabolic knowledge.

Our Concern in Plague Prevention.—Dr. EDWARD B. KRUMBHAR of Philadelphia read this paper saying that the present pandemic of plague, which had caused millions of deaths in the past 26 years, would be a constant threat to this country for another half century. Experience in this country for the last 15 years, and in the epidemic now prevailing in the Gulf States, comprised the opinion that antiplague measures should be directed chiefly against the rat, principally in the form of rat-proofing and rat survey.

Apoplexy.—Dr. CHARLES S. PORTS of Philadelphia said that many physicians believed that the lesion of cerebral apoplexy was always hemorrhage. This was not the case. By apoplexy we meant the occurrence of sudden paralysis, sometimes accompanied by unconsciousness, due to a lesion of the vascular system. This might be hemorrhage, the blocking of a vessel by a thrombus or an embolus, or closure due to spasm or to lacunar degeneration. Thrombosis or embolism was more common than hemorrhage. Sometimes it was impossible to determine the nature of the lesion. The fact that apoplexy was not infrequent in early life did not seem to be generally recognized. It was more frequent during the first decade of life than any other except the fifth. Syphilis was a frequent cause in young adults. Hemiplegia was not always present in apoplexy, the speaker said, for regions of the brain other than the motor might be involved.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

VENEREAL DISEASES. By J. E. R. McDONOUGH, M.D. 419 pages with illustrations. Published by William Heinemann, London.

BÆRETNING TIL INDENRIGS-MINISTERIET OM RATIONER-INGENS INDVIRKNING PÅ SUNDHETSTILSTANDEN. ved M. HINDHEDE. (The Influence of Rationing on the Health.) 107 pages. Published by Jacob Lund, Copenhagen, 1920.

SCURVY PAST AND PRESENT. By ALFRED F. HESS, M.D. 279 pages with illustrations. Published by J. B. Lippincott Company, Philadelphia.

AMEBIOB MOVEMENT. By ASA A. SCHAEFFER, M.D. 156 pages with illustrations. Published by Princeton University Press, Princeton.

TEXT-BOOK OF NERVOUS DISEASES. By CHARLES L. DANA, M.D. 566 pages with 262 illustrations. Published by William Wood and Company, New York.

THE SERBIAN EPIDEMICS OF TYPHUS AND RELAPSING FEVER IN 1915. By WILLIAM HUNTER. 153 pages with maps and charts. Published by John Bale, Sons & Danielsson, London.

HISTORY AND BIBLIOGRAPHY OF ANATOMIC ILLUSTRATION. By LUDWIG CHOULANT. 435 pages with illustrations. Published by the University of Chicago Press, Chicago.

OLD AT FORTY OR YOUNG AT SIXTY. By ROBERT S. CARROLL, M.D. 147 pages with illustrations. Published by The Macmillan Company, 1920.

LE LAIT CONDENSÉ. By Dr. P. LASSABLIÈRE. 151 pages. Published by A. Maloine et Fils, Paris.

HELPING THE RICH. By JAMES RAY. 107 pages. Published by Brentano's, New York.

CONTRIBUCION AL ESTUDIO DE LA AUTO-INTOXICACION INTESTINAL. By Dr. CARLOS JIMENEZ DIAZ. 138 pages. Published by Ruiz Hermanos, Madrid.

DIABETES. By PHILIP HOROWITZ, M.D. 196 pages with 27 text illustrations and 2 colored plates. Published by Paul B. Hoeber, New York.

THE SURGICAL CLINICS OF CHICAGO, October, 1920, Volume 4, Number 5. 231 pages with 46 illustrations. Published by W. B. Saunders Company, Philadelphia.

LES MUTILÉS DE LA GUERRE. By DOUGLAS C. McMURTRE. 188 pages. Published by Masson et Cie, Paris.

WARFARE IN THE HUMAN BODY. By MORLEY ROBERTS. 286 pages. Published by Eveleigh Nash Company, Ltd., London.

LE DIABÈTE SUCRÉ. Dr. MARCEL LABBÉ. 374 pages. Published by Masson et Cie, Paris.

MANUEL D'URETROSCOPIE. By ROBERT HENRY AND ANDRÉ DEMONCHY. 113 pages with illustrations. Published by Masson et Cie, Paris.

THE COURSE OF OPERATIVE SURGERY. By VICTOR SCHMEIDEN, M.D., and ARTHUR TURNBULL, M.B. 349 pages with illustrations. Published by William Wood and Company, New York.

THE COMMUNITY HEALTH PROBLEM. By ATHEL CAMPBELL BURNHAM, M.D. 149 pages. Published by the Macmillan Company, New York.

THE RADIOGRAPHY OF THE CHEST. By WALKER OVEREND, M.D. 119 pages with illustrations. Published by C. V. Mosby Company, St. Louis.

THE ROCKEFELLER FOUNDATION ANNUAL REPORT, 1919. 447 pages with illustrations. Published by the Rockefeller Foundation, New York.

A LABORATORY MANUAL OF ORGANIC CHEMISTRY FOR MEDICAL STUDENTS. By MATTHEW STEEL, M.D. 284 pages. Published by John Wiley & Sons, New York.

INSTINCT AND THE UNCONSCIOUS. By W. H. R. RIVERS, M.D. 252 pages. Published at the University Press, Cambridge.

56TH ANNUAL REPORT OF THE TRUSTEES OF THE BOSTON CITY HOSPITAL. 101 pages.

THE MAJOR SYMPTOMS OF HYSTERIA. By PIERRE JANET, M.D. 345 pages with illustrations. Published by the Macmillan Company, New York.

Miscellany.

Feeding Starving Children in Vienna.—The American Relief Administration, preliminary to undertaking its work of giving a noon meal six days a week to the school children of Vienna, made a medical examination of 207,000 of its prospective wards. As a result of this examination they separated the school children of the Austrian capital into four categories of health, as follows:

Sufficiently nourished	7,000
Undernourished	20,000
Badly undernourished	83,000
Badly undernourished and diseased...	97,000

Of 58,849 children examined at Dr. von Pirquet's infirmary during 1918, only 4,637 were judged to be of satisfactory health. The necessary food minimum to maintain vitality is about 2,000 calories per capita per day. Last spring Vienna's daily ration, according to a schedule furnished the American Red Cross by Dr. von Pirquet, was as follows:

Bread	6½ ounces	360 calories
Flour	2 "	180 "
Sugar	1 "	98 "
Potatoes	2¼ "	60 "
Fat	¾ "	152 "
Beef	½ "	24 "
Horse Flesh	⅓ "	6 "

Daily total 13 ounces 880 calories

The American Red Cross, working in conjunction with other relief agencies, has done and is doing heroic work in the effort to relieve this deplorable state of affairs, especially among the children.

Doctor Francisco Valles, Spanish Precursor of Bacon and Descartes.—Under the title "The Golden Age" Garcia del Real published a serial article in *La Medicina Ibera* which is completed in the issue of June 19, 1920, xi. 1. The number is devoted to Doctor Francisco Valles, physician, the first edition of whose large volume on philosophy appeared in 1587. A copy of this edition is to be found in the San Isidro library at Madrid. The work is ostensibly a rational commentary on the Bible and is regarded by the author as a superior contribution to Spanish science. Bullon, a modern Spanish writer, includes Valles among the Spanish precursors of Bacon and Descartes. The latter is said to have borrowed freely from both Valles and Gomez Pereira, a fact noted at the time by Huet, bishop of Avranches. Pelayo also showed that Descartes had quoted Valles almost verbatim without giving credit. The character of the matter which Descartes borrowed was psychological, such for example as the wisdom of doubting in approaching a given problem. Valles was a mechanistic philosopher, like his successor, and instead of antagonizing scriptural claims, which would have been impossible in Spain, he sought to sustain his contentions by scriptural quotations. He insisted that psychic force does not dominate the physical organs of the body, which obey a force proper to themselves, and hence he would be termed a Christian materialist. He cites in his book the success of Ponce in teaching congenital deafmutes to converse. In regard to Bacon, Valles wrote a work published in 1564—"Controversiae

medicæ et philosophicæ"—when the English philosopher was but three years old, in which the excellencies of the experimental method are systematically proclaimed. The author, however, does not accuse Bacon of having borrowed from him.

Childhood of Laennec.—The current French periodicals still contain numerous accounts of Laennec with especial reference to the lesser known phases of his biography. This publicity is well merited, for a study of the life of the pioneer shows that he lacked no single element of greatness as a medical man. Thus far he has not received his due from the "encyclopedists" and does not there rank among the very greatest medical men, but this omission will doubtless be made up to him in the future. *La Presse Médicale* for October 6, 1920, xxviii, 72, contains an account of Laennec's childhood. In 1788, with a younger brother, he was sent by his widowed mother to a paternal uncle at Nantes, who was a well known physician and who deserves full credit for the initiation of his nephew into the medical profession. Guillaume Laennec, uncle, was no ordinary man, for he was rector of the Medical School at Nantes. At this period the future diagnostician was but 7 years old and was placed in succession in a boys' school and the College of Oratory, where he made a brilliant record. The French Revolution was then in the air and appeared to confer a special license on the younger Laennec, who gave free vent to his heart's desires. He indulged in all permissible activities but at this period was but 12 years old and of course quite irresponsible. The Revolution came to Nantes and the uncle was placed in charge of the Military Hospital, improvised from the old city institution. It was at this juncture that the nephew elected the medical course in place of the Polytechnic School, which in peaceful times he would doubtless have chosen. The Revolution had suppressed the Faculties, but two earnest students improvised courses in dissection, and here the youthful Laennec, at the age of 15, began his medical studies. He also took upon himself the study of minor surgery, and soon after received his appointment as military surgeon in the Revolutionary Army.

Abuse of Medical Charity.—The *Drug Trade Journal* calls attention to the abuse of medical charity, using New York City as the basis of computation. The 46 hospitals not maintained by the city reported, last year, that they provided 600,000 persons with free treatment for a total of 1,203,728 treatments, for which neither the beneficiary nor the city paid a cent. Many other cities reported similar conditions. If statistics were available from the clinics and hospitals of the entire country, they would show that, despite universal employment at the highest wages the world has ever known in the history of man, from 3,000,000 to 5,000,000 inhabitants of this Utopian nation last year beat the doctor out of his bread and butter by seeking and receiving free medical and surgical treatment at these dispensaries of medical and surgical charity. Figuring an average of two treatments to a case at only \$1 a treatment, we have lost \$5,000,000 to \$8,000,000 we ought to have had. No other business or profession, the *Journal* holds, tolerates such a loss without making a concerted effort to check it.

THE DELICATE, NERVOUS, AND BACKWARD CHILD AS A MEDICAL PROBLEM.*

By E. BOSWORTH MCCREADY, M.D., F.A.C.P.,

PITTSBURGH, PA.

THE normally effective adult, functioning physiologically, and in harmony with his environment, is the exception in modern life and, consequently, the activities of the medical profession are largely concerned with supplying crutches to the "lame ducks" of society. We admit with the melancholy Dane that "the times are out of joint" and will allow the blame for the situation to rest upon capitalism, labor, prohibition, the war, woman's suffrage, the League of Nations, or the Democratic party, as our personal interest or bias dictates, but the solution does not lie in the elimination of any of these.

One of the few beneficent results of the world cataclysm from which we are emerging is a realization of the physical and mental shortcomings of a large portion of the population and a growing consciousness of the necessity for the cultivation of sound physical, nervous, and mental health in those whose shoulders must bear the burdens of the civilization of the future. It is truistic to state that the efficiency of the individual depends primarily upon the condition of his health, for while effective constructive work has been performed by those who were physically far from robust, if not actual sufferers from disease (Stevenson, Darwin, Spinoza, Bacon, Descartes, Kant), and much that is best in civilization is due to those whose mental health, at times at least, was by no means sound (Cromwell, Lord Clive, Luther, Goethe, Dean Swift), these sporadic cases of genius are exceptional; such individuals are the inspiring forces of civilization, but it is those with *mens sana in corpore sano* who furnish the dynamic impulse for progressive growth.

The medical profession, in the field technically known as that of preventive medicine, and through its conventional function of the treatment of diseased states, is doing much to fit the environment to the individual, and to return him, when afflicted, to his accustomed status in as sound a condition as possible. There is one function of preventive medicine, however, that has not received the attention it deserves from the profession generally, *i.e.* the prevention and correction of variations in physiologic and mental functioning in early life, before serious deviation becomes established.

*Read by invitation before the Medical Society of the District of Columbia, October 27, 1920.

The majority of neurotics, psychopaths, and physical ineffectives are characterized by an inferiority of constitution which is the end result of a series of factors initiated in early childhood and even before birth. Were these factors recognized sufficiently early and the proper steps taken to correct or counteract them, many lives of misery, dependency, and inefficiency would be saved.

Tuberculosis, the authorities tell us, affects both robust and delicate, the robust if they continue a hygienic mode of existence, recover, often in ignorance of their infection; the delicate, those with the physical habitus so often described, succumb. Exophthalmic goiter and other forms of thyroid and ductless gland disturbance occur, usually, in individuals who have shown in early life definite signs of constitutional inferiority relating to the endocrine system. The gastric neuroses, as the histories of patients so afflicted show, have their inception in some manifestation early in life. Other forms of neurosis, the psychoses as well, and various both well-defined and vague, functional and somatic abnormalities may be included in the list of diseases and conditions which show their danger signals early in life, at a time when the intelligent application of the principles of modern scientific medicine may accomplish much in the way of both prevention and cure.

It would seem logically that the physician is the one who should direct and supervise the application of the closely interrelated medical, hygienic, and educational measures necessary for the proper treatment of the class of children referred to in the title of this paper, though the busy general practitioner, pediatrician, and neurologist seem to have neither the inclination nor the time to give the detailed attention required. Parental fears are easily allayed when, as seems to be the custom, a trusted family physician or consultant, after casually looking over a distinctly constitutionally inferior child, states that he can find nothing "organically wrong" (meaning thereby, I suppose, that he discovers no disease entity) and dismisses the patient with a diet slip, a tonic, and a few vague directions to take the child out of school, get him into the country and he will "outgrow it." This attitude of *laissez faire* is responsible for more wrecked lives than the actual dishonesty of the charlatan, and one of the results is that parents who remain unconvinced immediately utilize the services of the regular irregulars, of the osteopaths, chiropractors, and miracle workers of various cults. Some ten years ago the writer, recognizing what he felt to be a need, decided that the field was sufficiently comprehensive to be worthy of a place in the sun as a branch of medical practice with a distinctive appellation of

its own, and after conferring with a leading authority on medical terminology, suggested the term "pædology," defined as "that branch of pediatrics in which the physical and mental defects of child development are especially studied and treated by the physician." The defects with which the pædologist deals are the result of interference, from many and diverse causes, with the normal processes of growth. These causes are hereditary, environmental, or a combination of both. Either class of causes may predominate as an etiological factor in a given condition, or group of conditions; seldom is either found alone.

The causes of constitutional inferiority are concisely stated by Noble as follows:

HYPOPLASIA OR DEGENERATION.

(Schema drawn for the author by Dr. Charles P. Noble.)

(a) Hereditary hypoplasia. Due to defect in the chromosomes (the chromatin or hereditary material) of the ovum or the spermatozoon of parents.

(b) Environmental hypoplasia.—(1) Due to toxemia in the parent or parents affecting (by poisoning) the ovum, or the spermatozoon, or both—giving rise to a defective (poisoned) impregnated ovum or germ. Preconceptional environmental hypoplasia or arrest.

(2) Due to toxemia in the mother or to local disease in the endometrium, leading to poisoning of the germ, the embryo, or the fetus, or to insufficient nutrition of the developing ovum. Antenatal, intrauterine hypoplasia.

(c) Mixed hereditary and environmental hypoplasia.—Due to toxemia in the parent or parents, themselves examples of hereditary hypoplasia, before conception; or to toxemia, or to uterine disease, in the mother during pregnancy; or to bad environment leading to disease in postnatal life, in children of parents having hereditary hypoplasia.

"Hereditary hypoplasia was formerly spoken of as the hereditary diathesis or dyscrasias, as gout, diabetes, tuberculosis tendency, the nervous diathesis, embracing hereditary neuroses and psychoses, and including epilepsy. It also embraces the hereditary tendencies due to defects or to reversion of the 'born criminals' of Lombroso, and the 'moral or sexual degenerates' of Krafft-Ebing. With exceptions, those suffering from hereditary hypoplasia are either continuously hyperenergized or are alternately hyperenergized and lethargic—or in the Wanderlust group.

"Environmental hypoplasia may be general or specific as to organ or systems of organs, or diathetic in type. Environmental hypoplasia is invariably associated with a lessened capacity to develop energy. The entire group suffering from environmental arrest are subenergized."

Much of the existing disagreement regarding the relative importance of the effects of hereditary and environmental influences in the etiology of defective development results from the current confusion as to the limitations of each of these factors. The term "hereditary" is often used when "congenital" or "fetal" should be employed as "hereditary syphilis," which disease is never hereditary in the scientific meaning of the term. Any conditions not existing in the germ cells of the parents before conception are due to extraneous influences and cannot be considered as hereditary causes. Whether the essential

potentialities of the germ plasm are *permanently* modified by accidental influences or not is immaterial; debilitated, toxin-ridden parents procreate debilitated, asthenic babies, who die, or, if they happen to survive, grow up weaklings, unfit to cope with the storms, stresses, and infections of modern civilization, and become in turn the parents of other weaklings, and so on down to the extinction of the line, or until Hygeia interferes. Because humanity forbids the full operation of the laws of natural selection it is necessary, for the preservation and development of the race, that the weaklings be eliminated, not by the methods of savage tribes and of some of the older civilizations, by subjecting to death through exposure the supposedly unfit, but through applying to each individual, early and continuously, the intensive effort necessary to insure physical and mental equilibrium to their highest potentials.

Early interference with the natural forces of growth by any vitiating influence modifying cell development becomes aggravated by reason of the interrelation and interdependence of the various systems of body cells, among the most important of which are those initiators and regulators of correlative growth, the ductless-glandular and vegetative-nervous systems. The result is further growth disturbance in the developing embryo. The cells of the endocrine system, imperfectly vitalized, fail to secrete as they were destined and the ensuing deficiency in hormonal stimulation results in further defective development, in organic inferiority, hypoplasia, infantilism, degeneracy—call it which you will—in varying degree. Hypoplasia may affect any organ and any structure in any degree from the grosser manifestations of abnormality to occult variations in cellular and chemical complexity, from general or local arrest to simple depreciation in vital force function.

Among the gross somatic manifestations of hypoplasia may be found:

1. Abnormalities in size and shape of the head. Softness or bossing of the cranial bones. Marked gaping or premature closure of the fontanelles and sutures. Undue distention or sinking of the fontanelles.

2. Malformation of the ears. Irregularity in size. Undue prominence or flattening. Misshaped helix, anthelix, tragus, antitragus, and lobule. Supernumerary auricles, auricular appendages, or atresia auris.

3. Anomalies of the eyes or lids. Drooping of one or both eyelids. Epicanthus and palpebral fissures. Congenital cataract, coloboma iridis or ideremia. Microphthalmus or anophthalmus. Strabismus and nystagmus.

4. Malformation of the nose. Saddle-shaped, exceptionally small and broad, or unduly large and prominent. Partial or complete atresia of the posterior nares.

5. Malformation of the face. Undue prominence of the cheek bones with markedly retracted small chin. Clefts of face and lips. V-shaped or high vaulted palate. Enlarged, protruding, and often cracked tongue. Irregularly shaped and implanted teeth, deficiency or excess in their number. Inability to bring jaws closely together, owing to irregularity of dental arches.

6. Malformation of long bones. Curvatures of the bones of the upper and lower extremities. Supernumerary fingers and toes or deficiency in their number. Syndactylism or fan-shaped distribution. Disproportion in size of legs and arms. Talipes, spina bifida, and caudal formations.

7. Umbilical hernia; diastasis recti abdominis. Anomalies of the genitalia; epispadias and hypospadias. Malformations of the anus and rectum. (Sheffield.)

The gross stigmata of degeneracy, just described, as well as those of minor degree to be described later, are the somatic manifestations of hypoplasia. It may some day be possible, when our knowledge of endocrinology has become more complete, to trace, by means of the stigmata of degeneracy, the retardations and exacerbations in function, changes in chemical complexity, and even the structural abnormalities of individual glands of internal secretion, even back to early intrauterine existence. More even than this is possible as a result of an enlightened knowledge; it may be that the mysterious directive forces of hereditary transmission will be found to reside, not in the essential structure of the chromatin, but in the intricate chemical (hormonic) constituency of the cells.

Pertinent to this statement is the recent address of Prof. Arthur Keith before the British Association for the Advancement of Science, in which he thoroughly canvasses the situation in reference to the effects of the internal secretions in causing those primary differences which distinguish the principal races of mankind. He maintains that the endocrine glands not only serve the purpose of immediate regulation, but more fundamentally they govern to a great degree the ontogeny of those human traits which for the most part are used for differentiating the several races.

Stigmata less obvious than those enumerated in the table above are found in constitutionally inferior individuals, particularly in those whose inferiority is not grave enough to constitute actual bodily deformity or mental deficiency but is sufficient to interfere with the efficiency of the individual so affected.

These incidental variations in development, as they may be termed, are: (1) Anatomic, (2) Physiologic, (3) Psychic.

Among the anatomic variations are found: retardation in growth rate, bodily disproportion, underweight or obesity, hypotonicity of muscles and ligaments, hypertrichosis and abnormal distribution of hair, long slender bones, delayed epiphyseal union, muscular ocular anomalies, astigmatism, myopia, hypermetropia, deflected nasal septa, enlarged turbinates, high arched palate, adenoids and enlarged tonsils, maxillary or mandibular prognathism, widely spaced teeth, defective teeth, postural defects, visceroptosis, anomalies of bones of inner skull, small or malformed sella turcica, enlarged thyroid, abnormally small thyroid, persistent or precociously atrophied thymus, underdeveloped genitalia.

Among the physiological variations may be mentioned: cold, clammy skin and cold extremities, subnormal and unstable temperature, low blood pressure, undue dryness of skin and undue sweating, localized flushing and pallor, anemia, reduced output

of urinary solids, enuresis, variations in cardiac rhythm, constipation, gastric irregularities, delayed puberty, dysmenorrhea, tremors, incoordinate muscular movements, defective articulation, stammering.

Among the psychic variations may be included: aprosexia and psychasthenia (the natural correlates to a condition of general adynamia); hypermotivity, perverse tendencies (delinquency, sex perversion, inversion, etc.), a sense of inferiority, negativism, egocentricity, isolated depression of function of higher cerebral centers (congenital word-blindness, word-deafness, amusia, etc.), night terrors, food idiosyncrasies, premature eroticism, sexual frigidity, sex complexes, obsessions, compulsive ideas, phobias, etc.

The treatment of constitutional inferiority may be divided into: (1) Prophylactic, (2) Hygienic, (3) Medical, and (4) Educational.

Prophylactic measures should date not only from the earliest moment of conception, but from a time much earlier than this in accord with the dictum of Oliver Wendell Holmes that "the education of the child must begin with the grandparents." Accordance with the rules of hygienic living on the part of prospective parents will do much toward insuring the integrity of individual germ cells. After conception the burden of responsibility rests upon the mother. The importance of antenatal hygiene is not generally realized, though upon its proper observance depends, in a large degree, the stability of the race. Malnutrition, either from insufficient or improper food, or the result of metabolic disorders, focal infections, or intestinal toxemia, is a frequent source of hypoplasia in the developing embryo. Modern scientific medicine does not recognize "maternal impressions" as a plausible factor, but the emotional state engendered by belief in this popular superstition is in itself a baleful influence through its effect upon bodily functions. Worry and emotional disturbance from other causes, and exhaustion from overwork and an over strenuous pursuit of pleasure, are also possible factors. An important measure in the prophylaxis of hypoplasia originating during the gestational period is through treatment of endocrine insufficiencies in the mother by means of ductless gland preparations as advocated by Dr. Sajous. Every prospective mother should be carefully examined for evidence of lues, and intensively treated as indicated. Equaling prenatal prophylaxis in importance is that during the period of infancy, as nutritional disorders during this period frequently cause interference with the forces of correlative growth. The writer is convinced that the malnutrition and toxemia incident to gastrointestinal disturbances in infants constitute, with the possible exclusion of prenatal causes, the most frequent cause of constitutional inferiority. The histories of delicate, nervous, and backward children (not inherently defective) almost invariably present a record of intestinal infections during the first year. Unusual care to prevent the occurrence of these must be exercised when maternal nursing is not possible, not only because of the dangers incident to artificial feeding, but also for the reason that the inability of the mother to nurse the child is usually due to the fact that she herself is constitutionally inferior and consequently fails to trans-

mit to her offspring the vital force necessary to the energization of the processes of normal growth. Recent studies in nutrition have shown the necessity for incorporating in the diet of the developing child food substances rich in vitamine content and in mineral salts. Constitutional inferiority is often a true deficiency disease due to a diet deficient in vitamins or other food accessories necessary for growth and development. The physiology of metabolism is in process of being rewritten and it now looks as though in the very near future we will definitely know something of the processes involved. The writer has for a long time been convinced that much physical and mental instability in late childhood is due to early dietary habits and has lost no opportunity to protest against the customary high carbohydrate diet of infants and young children. Feeding for correlative growth involves more than mathematical formulæ supported by the elusive vitamine in fruit and vegetable juices. The development of all the tissue of the body is dependent upon the nutrition of the individual cell and the nutrition of the cell depends upon a pure rich supply of blood. Many cases of subnormal development are due to an impoverished blood supply, the result of various factors, one of the most important of which is an excess of carbohydrates in the diet. In support of this contention may be mentioned recently published experiments upon blood regeneration at the Harper Foundation for Medical Research in the University of California, in which Whipple and his associates have clearly demonstrated the profound effect of food factors on blood pigment regeneration. They found, in their experiments on dogs, that rapid and complete blood regeneration follows only when animal tissues are included in the diet. They found cooked lean beef, beef heart, and liver to be effective, while the commercial and fresh water-extracts of these substances were impotent. They also found that a hemorrhagic animal will actually form more red cells and hemoglobin during fasting than during a similar period of sugar feeding. Whipple, Hooper, and Robscheit point out that since in neither case nitrogenous material is taken into the body, whatever hemoglobin and red cell stroma may be found must be constructed in the organism from body protein or protein split products. Thus the well-known protein-sparing action of carbohydrates tends to protect the body from protein loss and so prevents the formation of catabolic "fragments" which would ordinarily be available to form new blood cells. These investigations tend to confirm the personal observations of the writer, who has found that though constitutionally inferior children will slowly grow and gain in weight on a diet free from animal proteins, they will remain anemic, while they will develop at a more normal physiologic rate, with more or less rapid blood regeneration depending upon other factors, when animal tissues are added to the diet. For several years a group of children under his observation were maintained on a diet free from animal tissue proteins, the caloric value and proportion of proteins, fats, and carbohydrates being accurately regulated, yet this group failed to show the nutritional improvement which did a later group on an unestimated diet, containing animal tissue. It was also noted that digestive disturbances were no less frequent than with the latter diet,

in which there was little restriction upon substances often forbidden to children. The digestive functions of the child, like other functions, develop through exercise, and the writer is of the opinion that many juvenile and adult ills are traceable to pampering of this important function in early childhood. Nature signifies when chewing should begin by the eruption of the teeth, and if it were more generally the custom to give solid food, judiciously, of course, to babies toward the end of the period of infancy there would be less teething disturbances and less digestive ills in childhood and later life. A certain amount of dietetic liberty in early childhood also is preferable to the alimentary coddling with which many children are afflicted.

Ordinarily, children, even those of the well-to-do, have not enough to eat. A child of twelve years, receiving the proper amount of exercise and fresh air, can easily consume an amount of food furnishing 3,500 calories a day, a quantity sufficient to maintain an adult at hard labor in good health. The fears of solicitous parents, supported by popular books and articles on the feeding of children, lead to restrictions in the diet which results in a state of malnutrition as serious as that occurring in families of slender means. Again, the school child, in the habit of sleeping until the last minute, comes to the breakfast table with time only to bolt one or another emulsified cereal whose only virtue is that it requires a large quantity of milk or cream to permit of being swallowed. By the middle of the morning his tissues crave more nourishment, which craving is relieved at recess time by candy or highly ornamental pastry of low nutritive value. The edge of his appetite blunted, he makes a hasty lunch, grudging the time that might be used in play. Again in the afternoon his appetite is impaired by some easily obtained carbohydrate food, and at dinner time he partakes only of those dishes for which he has great liking. The result is that his diet, while not necessarily deficient in calories, is composed largely of carbohydrates, causing an evanescent energy but failing to provide for tissue wear and tear, for blood genesis, for growth, and for storage for emergency.

Next to diet, fresh air, and not merely "fresh air" but air in motion, bathing, proper hours of sleep, exercise, clothing, all have an important place in the prophylactic and hygienic management of the hypoplastic child. It is time for us to apply to the raising of children the lessons learned on the stock farm, in the raising of domestic animals and fowls. The stockman has learned that the three prime requisites for success, the stock being sound, are diet, fresh air, and exercise. He knows that to secure the maximum of growth and vigor he must feed a ration well balanced as to proteins, fats, and carbohydrates; that he must furnish sufficient roughage to give bulk to the intestinal contents; that he must give green stuffs and food rich in vitamins and mineral salts, and that in case of the omnivora, as hogs and chickens, he must, to get the best results, give tankage (dried blood) and beef-scrap. He knows that he must feed in large quantities and must allow his stock a certain amount of choice in their selection of food substances, they being better able to determine the proper proportions than he, and that to gain the maximum of growth and vigor,

they must have open range, free from crowding, from undue noise and confusion. To the urban realist "pigs are pigs," but to the up-to-date farmer profitable pigs are a combination of balanced rations, exercise, and fresh air. Every observant swineherd has seen the "runt" of the litter, nosed aside by his stronger and more active brothers and sisters, equal or outstrip them all when given a trough and a run to himself.

The prevalent impression that purely medical measures are of secondary and doubtful importance in the treatment of the class of cases under discussion is both a cause and a result of the indifference of the medical profession generally concerning this important phase of preventive and remedial medicine, and is responsible for the pre-emption of the field by the lay psychologist and pedagogue who, while perhaps well-grounded in the principles of psychology, lack, because of the nature of their training and experience, a broad medical viewpoint. Infinitely more serious, this indifference has driven these patients into the hands of Christian Scientists, osteopaths, chiropractors, and other advocates of various fads and fancies. The first requisite to effective treatment is the removal of possible sources of focal infection and reflex irritation, both of which are potent factors in the production of hypoplasia, not only through their immediate irritative and toxic effects upon the vegetative nervous system, but also because through long continued overstimulation of the adrenal system they cause a secondary adrenal depletion, a hypoadrenia, similar in its effects upon correlative growth to the adrenal deficiency following the acute diseases of childhood. Thus the surgical removal of adenoids and diseased tonsils, eyestrain, phimosis, impacted cerumen, carious, impacted, and abscessed teeth, etc., is an important therapeutic procedure, whose corrective influences are both immediate and remote. An important surgical measure is the relief of increased intracranial pressure by means of cranial decompression, as cerebral hemorrhage in early life is a productive cause of mental and physical instability. Rodder has pointed out that the prevalent impression that cerebral hemorrhage follows only difficult labors and instrumental deliveries is fallacious, and that hemorrhage may follow normal labor when least expected. He advises that early surgery be controlled by measurements of the coagulation time of the blood, and that fresh blood be used therapeutically before operative procedures are instituted.

Practically every organically inferior child presents symptoms which are referable to the endocrine system, to the vegetative nervous system, and to the bloodmaking apparatus.

The clinical syndrome in young children is usually one of suboxidation furnishing definite indications for therapeutic intervention. The low blood pressure, lowered basal metabolism, cold hands and feet, general asthenia, and hypotonicity point conclusively to lowered activity of the adrenal system. This endocrine implication usually includes the thyroid and pituitary as well. Through the use of a number of well-known drugs, among which mercury, strychnine, caffeine, and digitalis may be cited, the adrenals may be stimulated to increased activity; and in cases in which the hypoadrenia is develop-

mental in origin these drugs may be given to advantage, but in those in which the lessened activity is the secondary result of an acute or chronic hyperactivity such "whips" should be avoided. In these, and they are the most common, the burden should be taken off the adrenals, by adding to the adrenalin content of the blood, and by a vicarious stimulation of metabolism, though the use of adrenalin chloride, hypodermatically or by mouth, and the administration of suprarenal gland, which may be advantageously supported with small doses of thyroid, and with pituitary and the gonads. Syphilis in the forebears is prone to affect the endocrine glands in the descendants, either as an active infection or the sterile end of a result of a degenerative process. In these cases, particularly, is mercury indicated, with small doses of thyroid or iodine to enhance its activity. In the writer's opinion arsenicals, because of their depressing action upon the chromaffin system, should not be used in congenital lues except in early cases with active lesions, and in juvenile neurosyphilis when mercurial treatment has failed of results.

A natural result of suboxidation is a reduced alkalinity (deminerallization) of the body tissues, which may reach a crisis in a frank attack of acidosis. Cyclic vomiting in children, sudden acute prostration with pallor, or sudden temperamental changes without potent cause, should always lead to examination of the urine for acetone. A vial of blue litmus paper to test the reaction of the saliva would in most nurseries be of greater value than the omnipresent clinical thermometer, as alkaline deficiency early manifests itself in the buccal secretions. Acute acid conditions must be met by the exhibition of alkalis, but the rational method of therapy is to remove the cause through the sustained stimulation of tissue oxidation.

As the equilibrium of the vegetative nervous system is in a large degree controlled by the chromaffin system, it is evident that impairment of function of these organs leads to imbalance of function in the vegetative nervous system. According to Falta, "The ductless glands themselves are vegetative organs. They are supplied by vegetative nerves and possess, therefore, central projection fields. It is assumed that the function of the ductless glands is in great measure regulated by the nervous system." Again, "The ductless glandular system influences the excitability of the vegetative nervous system by the hormones that it gives off to the circulation. At least this is true in regard to adrenalin, and is in all probability true of the other ductless glandular hormones." Atropine or belladonna in full physiological dosage is sometimes a valuable remedy because of its sedative action upon vagotonic irritability in some of the conditions to which the constitutionally inferior are subject, particularly in asthma, hay fever, and enuresis due to cystic irritability. I have found both atropine and adrenalin useful in some varieties of stuttering due to a spastic condition of the respiratory organs originating when the effort is made to speak. These patients almost invariably are suboxidized and the most important factor in their treatment is the correction of the perverted metabolism. The contentions of some psychologists and lay speech experts that stammering is essentially a psychic manifestation with-

out physical basis is absurd. Psychic factors intrude to effect fixation and continuance of the habit, but the initial etiological problem is one of perverted physiology. There is a large class of unstable children, apt to be mentally alert, though superficial, who present symptoms referable to thyroid toxicosis. These respond well to proper regulation of hygienic influences, including diet, to rest, and to small doses of the bromides, long continued, and to arsenic.

In all cases other evidence of endocrine abnormality or dyscrasia should be carefully searched for and, when found, the appropriate remedies should be exhibited. Thus hypopituitarism in a mild degree of dystrophia adipososexualis is not uncommon and should be treated by increasing oxidation by the methods already alluded to and by the use of pituitary extract, which substance is rich in phosphorus (nuclein) and chromaffin tissue. In these cases, as in others marked by athenia and suboxidation, thymus gland is useful, supplying as it does (according to Sajous) an excess of phosphorus to the tissues during the period of growth.

An almost constant accompaniment of constitutional inferiority is a hemic dyscrasia, the evidences of which the writer is in the habit of referring to as "hypoplastic blood," blood which is ontogenetically incomplete—more or less of the fetal type. The hemoglobin is low, and in the cover-glass specimen is unevenly distributed, the red cells are decreased, are irregular in shape and size, and nucleated red cells are present. The leucocytes may be increased in number when there is toxemia, or deficient in number, and myelocytes may be present. Almost invariably there is lymphocytosis and an increase in the eosinophiles. The blood dyscrasia, being both a cause and a result of defective correlative growth, must be met by stimulation of the blood-making organs to increased activity. This indication is in a degree met by the hygienic and medical treatment mentioned above. Iron, a specific stimulant of bone-marrow (Nageli), is a valuable adjunct to treatment. The writer prefers the hypodermic administration of iron in the form of the green citrate, but in intractable cases uses in addition reduced iron, tincture of the chloride, iron carbonate, and organic iron in the form of the various preparations of hemoglobin now on the market. If the hemoglobin of the blood fails to improve satisfactorily after the exhibition of one form of iron, another should be substituted, as failure with one preparation may be followed by brilliant results when the dose is materially increased or another preparation is used. To stimulate the formation of leucocytes in the spleen, spleen substance may be given with advantage.

The educational management of constitutionally inferior children might be considered to be outside the legitimate domain of the physician, yet when we realize that education (according to the New Standard Dictionary) "includes not only the narrow conception of instruction, to which it was formerly limited, but embraces all forms of human experience, owing to the recognition of the fact that every stimulus with its corresponding reaction has a definite effect upon character," we see that the term is practically synonymous with the current concept of the term "mental hygiene." As every act of the

child's life, every impression, is a factor in the systematic development of the powers of intellect, feeling, and conduct, it is important that to an extent the environment of the inferior child be intelligently regulated by one who is cognizant of his constitutional variations and who may, from them, postulate and understand his psychic eccentricities, real or potential.

While the writer wishes to stress the role of the constitutional basis in the etiology of nervous and mental disease and in conditions of chronic invalidism, he does not ignore psychic factors as an important contributory cause. In his opinion, however, the psychic factor, to be of etiological significance, must ordinarily be grafted upon an organic basis. Undoubtedly, psychic shocks, sudden or long continued in lesser degree, do initiate serious abnormality. However, in the main, both the susceptibility and the response to psychic trauma are conditioned by the somatic integrity of the individual. The writer must confess that his mind does not go along with those who attach a supreme importance to mental conflicts, submerged desires, and the usurpation of the unconscious in early life. That these manifestations of an abnormal mental life exist he does not doubt, that they are serious sources of danger if allowed to persist he does not deny, but that they constitute the prime force to be reckoned with he cannot admit. Considerable experience with children, normal and abnormal, has led him to believe that sexuality in its protean forms is an important phase of early child life only when abnormality of the nervous system exists, and that the persistence of abnormal infantile sexual traits into adolescent and adult life occurs only in individuals whose soma and psyche have not fully and evenly evolved; in other words, in those who are constitutionally inferior. Maeterlinck and Barrie draw a truer picture of the normal child's mind than does Freud; contamination, except in those of exaggerated sensual susceptibility because of nervous defect, comes from sophisticated companions and elders, not from essential depravity. There is no intention to deprecate the analysis and correction of abnormal psychic reactions, either those with sexual basis or otherwise, as a means leading to prevention or cure, but in the application of Freudian philosophy the importance of the treatment of the constitutional basis should not be ignored. Through the forces of suggestion and example come also, to a large extent, those crudities and perversities which lead some people to consider children as selfish little animals. Wisely directed, the same forces lead to idealism and altruism. The sense of inferiority common to hypoplastic individuals leads to accentuation of the fundamental primitive instinct of fear which Boris Sidis believes to be the source of all psychopathic maladies, and to the desire to escape from reality in phantasy, another important factor in psychopathy, in hysteria, drug and alcohol habit, crime, etc. These tendencies call for early educational measures directed toward counteraction and suppression. The unreasonable fears of children are usually initiated through suggestion on the part of the elders and can be eliminated by the rational application of the same means. Imagination in the child should not be suppressed, for this interferes with expression and leads to the shut-in type of personality and

other forms of abnormal mental life, but should rather be encouraged and guided. The child should never be allowed to let go his hold upon reality, to lose himself completely in the characters and events of his little dramas, but should be taught to retain a consciousness of the sharp dividing line between that which is "pretend" and that which is real. To do this interferes in no way with the child's enjoyment of the world of make-believe and it serves to ingrain in him the habit of keeping both feet on the ground. Fairy tales, myths, the exaggerations of fiction, and the hyperboles of social expression should be interpreted for him on this basis, and at a very early age he will learn to make his own interpretations and draw his own conclusions and at the same time will develop that most potent preventive of mental variation—common sense. Undue repression in early childhood is a prolific cause of the establishment of a sense of inferiority in the hypoplastic and also in those inherently within the limits of normality. While inculcating in the child the precept "there is no such word as can't" we should teach the parent that "don't" also is taboo. The child must learn through experience and his activities should be directed and encouraged, not checked at every turn. Unfortunately the average home, particularly the urban home, is conducted for the convenience of the adult members of the household; the children may fit in as best they can, just so they keep out of the way of their elders at the infrequent times when these have "no place to go"; or when it is otherwise they are liable to the opposite extreme of oversolicitude, overindulgence, and inconsistency of management as harmful in result as the species of neglect mentioned. The first step in the management of the hypoplastic child is that the domestic arrangements of the household be modified and changed as conditions require, sources of friction must be removed, impatience, irritability, and undue sympathy on the part of various members of the household must be curbed. The child's activities must be arranged to insure sufficient rest, as not only is easy fatigue a prominent symptom of organic inferiority, but it is also a contributory cause. Most children are overstimulated by the conditions of modern life, conditions which, because they are usual, are considered normal. Fatigue in children brings about a nervous irritability which leads to further effort giving the false impression of unflagging energy. Constant calls upon the reserves of energy, which should only be made in emergency, and in early childhood very infrequently result in nervous insolvency. The constant din of the city streets, the vibration of street-cars and automobile, the glare and excitement of the movie, the strident jazz of the phonograph, the constant hurry and bustle to be somewhere else as quickly as possible—all these have their effect for harm on the delicate organism of the growing child.

The ideal place to carry on the education of the hypoplastic child is the country, and if necessity compels city living, as many of the practicalities of rural existence as possible should be utilized. It is in the country that the child can confront the realities of existence in an uncontaminated state and be brought to realize what Cabot calls "the glory of raw materials," and it is there that the human plant may best be nurtured. As Browning says:

It was better youth
Should strive, through acts uncouth,
Toward making, than repose on aught found made.

The conventional cut and dried methods of the modern schoolroom, depending largely upon memory and abstractions, fail properly to hold and direct the attention of the hypoplastic child. Contact with the concrete, the study of the phenomena of Nature, and the demands made upon initiative and self-reliance resulting from a system of education in which the practical is largely utilized, serve to bring about function of normal areas of interest and to eliminate abnormal ones.

805 KEENAN BUILDING.

MYOMECTOMY VS. RADIUM AND X-RAY IN THE TREATMENT OF FIBROID TUMORS IN WOMEN UNDER FORTY YEARS OF AGE.*

By HIRAM N. VINEBERG, M.D.,

NEW YORK.

ATTENDING GYNECOLOGIST, MT. SINAI HOSPITAL; CHIEF GYNECOLOGIST, BETH MOSES HOSPITAL, BROOKLYN.

It seems to me the time is opportune for a discussion of the relative merits of myomectomy, and radium and x-ray, in the treatment of fibroid growths of the uterus in women who are still comparatively young, say, under forty.

There is no claim made by me to adduce anything new about the operation of myomectomy. As is well known, it has been practised for several years by most gynecologists and by some general surgeons; but the object of this short communication is to draw attention to what probably is *not* so well known, namely, that myomectomy is by far the more conservative procedure in women who have still some years to the menopause, than is either radium or the x-ray.

In the first one, there is conservation of the menstrual function; in the other two (if they are successful) menstruation ceases and all the distressing phenomena of the artificial menopause appear.

All of us who operate upon the genital organs of women learn early in our career to abate our joy at the successful issue of a radical operation, through the probable return of our patient afterwards, complaining of various nervous symptoms for which we can give them but little relief. In many instances there is no choice in the matter, as, for instance, in malignant disease and in hopelessly diseased adnexa leading to partial or complete invalidism.

Therefore it is that the conscientious and thoughtful operator nowadays makes every effort to preserve the menstrual function of his patient. I say, advisedly, menstrual function, for the ovaries to my mind serve no useful purpose when the uterus has been removed, or when the endometrium has been destroyed so that menstruation is no longer possible.

Some of the very worst cases of the artificial menopause syndrome have been witnessed by me in women who had their ovaries and their uterus *in situ*, but in whom a too energetic curettage had

*Read before the Section on Obstetrics and Gynecology of the New York Academy of Medicine, November 23, 1920. See page 120.

brought about a permanent cessation of menstruation. The same applies to instances when the uterus was removed and the ovaries left behind.

There is to be observed at the present time a singular state of mind on the part of medical men. They are all keenly alive to the importance of conserving the menstrual function in women. They hesitate, to their credit, to consign their patient to an operation which would destroy that function. Still, they will refer, without a moment's hesitation, a patient with a bleeding fibroid of the uterus, to the roentgenologist or radiologist, who can only be successful by destroying that function, and, in most instances, permanently.

For this state of mind of the medical profession, the gynecologist himself is mostly to blame. He has written and talked to a surfeit-degree about the various techniques in performing hysterectomy;—whether the cervix should be removed or should not, or whether in removing the uterus an ovary should be left or not, and about kindred details. But on the true crux of the matter,—the conservation of the menstrual function,—he has been rather silent. It remained for that deep medical thinker and great surgeon, W. J. Mayo, to bring the subject recently before the profession in a masterful and convincing paper, read before the Obstetric Section of the American Medical Association at its meeting of April, 1920, and published in the *Journal of the American Medical Association* for June 19, 1920. The perusal of this paper gave me especial pleasure, in that it expressed the views that I have held and the practice I have followed for many years past.

The statistics Mayo furnishes (and to no other operator are such huge personal statistics available) dispel the fear that myomectomy is a more dangerous operation than hysterectomy. In 617 cases of abdominal myomectomy in the Mayo Clinic, there were only three deaths, or 0.5 per cent.

My own statistics are very modest in comparison but are equally good. For a period of about the past ten years I have been able to collect 120 cases, 31 from my own private patients, and 89 from the Second Gynecological Service of Mt. Sinai Hospital. There was not a single death among the entire series.

In one of the hospital cases a hysterectomy was done shortly after the myomectomy, because the patient was running an elevated temperature, and an undetected sloughing submucous fibroid was found. This was among the early cases, when an exploration of the uterine cavity was not always practiced.

In a second hospital case there was an extensive breaking-down of the abdominal wound, with evident secondary suppuration of the wound in the uterus, as the patient has a small uterine fistula which however gives promise of closing soon.

This practically constituted all of the serious morbidity that occurred. The ages of the private patients ranged from 22 to 37 years. One was 42 years old. Nine, or 27.7 per cent. of the patients conceived afterwards. One had 2 children, seven had 1 child, and one resulted in interstitial pregnancy.

Five of the patients were pregnant and had to

be operated upon on account of acute symptoms due to degenerative changes in the growth. Two went to full term and gave birth to living children. In the remaining three the tumor invaded the uterine cavity to such an extent that after removal of the growth the uterine wound could not be coapted until the products of conception were removed.

All but two of the cases were operated upon through the abdominal route. The tumors, with a few exceptions, were large, ranging from the size of the closed fist, to growths reaching to the umbilicus and to midway between the umbilicus and ensiform cartilage. They were all interstitial or submucous. In none of the cases has there been a recurrence of fibroid growths or of menorrhagia.

The subsequent histories of the hospital cases, for obvious reasons, are not so well known. The follow-up system is of comparatively recent date and is far from being thorough. None, however, have been readmitted for secondary operations and those who have returned to the follow-up clinic showed no recurrence of growths. On bimanual examination no appreciable enlargement of the uterus was noted. Three were pregnant at the time of operation: in one the uterus was emptied at the time of the myomectomy; the other two went to full term and were delivered of a living child. In one of the latter a dermoid cyst of the right ovary was also removed.

Three of the patients, one of whom had been sterile before operation, conceived afterwards and went to full term with normal deliveries. Eight patients were operated upon through the vaginal route; the remaining eighty-one through an abdominal incision.

It is a surprise to oneself what apparently unpromising cases lend themselves to a myomectomy if one starts out with the determination to save, if possible, the uterus in whole or in part. I recall several, in which at first sight the size and the number of the growths and their situation were such that a conservative operation did not seem at all feasible; still, with persistence and patience I was able to remove the growths and build up a fairly satisfactory uterus.

Two of these cases are worthy of special mention: In one, the growth reached to three inches above the umbilicus and was situated between the fundus and the cervix. After its removal the body of the uterus was almost completely separated from the cervix, being united posteriorly by only a narrow bridge of tissue. I sutured the body to the cervix with plain catgut. The patient made a good recovery, menstruated normally and on examination a few months later the uterus felt like a perfectly normal organ. In the other, the growth, equally large, was situated in the same way, between the fundus and the cervix, but had also developed deeply and extensively into the layers of the broad ligament. When the growth was removed there was such a disturbance of the anatomic relations of the right tube and ovary that I deemed it wise to remove them, particularly as the left tube and ovary were perfectly normal.

What the operation meant to these two patients can readily be realized when it is borne in mind that they were both unmarried women, 32 and 35 years old respectively, who had immediate pros-

pects of marriage, provided their generative organs could be conserved.

One of the objections often raised against myomectomy is the frequency with which tumors develop later, requiring a second operation. In Mayo's series of 741 cases, only 19 (2.56 per cent.) required secondary operations. In 11 of the cases the operation was performed five or more years after myomectomy, and in 1, thirteen years afterwards.

We have seen that my own statistics in this respect, as far as they go, are even more favorable than those cited by Mayo. Thus far not a single case has had to be operated upon again although many of the patients were operated upon more than five years ago.

I have had occasion more than a few times to do a second operation upon patients previously operated upon by other surgeons, but in these instances the period elapsed from the prior operation was so short, and the growths were so large, that the impression gained was that the prior operator had contented himself merely with removing the pedunculated growths and had left untouched the equally large or larger interstitial ones.

A valuable point made by Mayo has reference to the advisability or necessity, in cases of hemorrhage, in addition to the myomectomy, of opening the uterine cavity and of thoroughly curetting the endometrium under the eye. In the majority of my cases this procedure was made unnecessary by one or other of the tumors dipping into the uterine cavity and being covered in great part directly by the endometrium. The difficulty in these cases was to conserve sufficient endometrium to carry on the function of menstruation.

But the value of the procedure was forcibly illustrated in a case recently operated upon by me. The patient had had profuse hemorrhages for a long period so that her hemoglobin was reduced to 38 per cent. At the operation there was found a growth the size of the closed fist, situated in the posterior wall. There were three smaller ones scattered over the rest of the uterus. When all the growths had been enucleated and the resulting wounds sutured, the body of the uterus still appeared rather large. However, no other tumor could be felt through the uterine wall, by the most rigid palpation. Nevertheless, I felt that those that had been removed would scarcely have caused such severe hemorrhages. I therefore cut through the wall of the fundus directly into the cavity of the uterus, and found the endometrium very much thickened, and spongy, and detected an elongated submucous fibroid of the size of one's thumb. The latter was easily removed with the finger and the endometrium was thoroughly curetted under the eye.

In spite of our strongest determination and most painstaking efforts, it must be admitted cases will now and then be encountered in which it is not possible to save the uterus. What we must endeavor to do, then, is to save enough of the organ and endometrium to carry on the function of menstruation.

Even should we be baffled in this and the entire organ have to be sacrificed, the patient would in no wise be any worse off regarding her menstrual function than she would have been had she been

successfully treated with x-ray or radium. On the contrary, to my mind she would be better off, for her cure would be more certain and more complete.

Let me not be misunderstood. I am not endeavoring to make out a case against x-ray or radium, as the title of my paper might indicate. They have their uses in the treatment of fibroids, even in young women. There are certain women to whom the dread of an operation is so great that they will go on suffering pain and loss of blood rather than submit to it. Such patients I refer to the roentgenologist or radiologist; also those who have a constitutional dyscrasia which would render an operation unusually dangerous.

I go even further. Every patient who consults me regarding a fibroid tumor causing symptoms, is told by me she may have her choice of treatment, either by operation, or by x-ray or radium. I tell her, regardless of her age, that the *one* (operation) perhaps carries more risk with it than do the others, but that in my opinion it is more certain of permanent cure. If she is under forty I try to impress her with the advantages, of which I myself am strongly convinced, of submitting to an operation, the endeavor of which would be to remove her tumor or tumors and preserve her menstrual function.

NOTE.—In the discussion, following the reading of the paper, exception was taken by Dr. Howard Taylor to the statement that operation carried with it more risk to life than x-ray or radium. He cited a fatal case following radium treatment. I myself recall a fatal case in the hands of one of the most expert radiologists in the country. No doubt other deaths have occurred. This scarcely could be otherwise, in view of the fact of the uncertainty in the diagnosis of abdominal tumors. The most expert and experienced diagnosticians frequently make errors in this field. Cases not infrequently occur of old pus tubes so intimately barked to the uterus that the resulting mass is frequently mistaken for a fibroid tumor. Every operator will recall several such mistakes in his own experience. Ovarian cysts with thick walls and malignant growths of the ovary are at times so extensively adherent to the uterus that they are mistaken for fibroid growths of the uterus. X-ray or radium treatment in these instances would be disastrous. Numerous other conditions could be cited, did space permit, in which a diagnosis of a fibroid growth is made and on opening the abdomen an entirely different condition is found.

751 MADISON AVENUE.

TUMOR OF THE SPINAL CORD AND ITS MEMBRANES.

BY NORMAN SHARPE, M.D.,

NEW YORK.

SURGICAL treatment of tumor of the spinal cord is of comparatively recent development. The first tumor of the cord was removed a little over thirty years ago. In the intervening years since this doubtfully-undertaken first operation, our knowledge of cord tumor has broadened, the signs and symptoms of tumor presence systematized, and the technique of the operation improved, so that correct diagnosis and successful removal of cord tumors is of frequent occurrence. From the large number of reported cases, there has been built up such a comprehensive symptom-complex of the various cord neoplasms, that it is now rather rare in diagnosis of cord tumor to have operation reveal not tumor but organic cord disease. Rather the error

lies in the opposite direction, for not infrequently tumor signs will so simulate organic cord disease, that operation is not thought of, and only at later operation, or at autopsy, will the presence of a tumor be disclosed. Such was the case in one of the patients reported in this article. In any patient with beginning motor impairment of the lower extremities and even slight sensory disturbances, with lues excluded, the strong probability of a spinal new-growth must be constantly kept in mind. Naturally, when the signs point to the presence of a tumor, operation is the only procedure. In a doubtful case where the signs are confusing, indicating either tumor or organic cord disease, an exploratory laminectomy should always be done. Even in cases where the signs are largely those of organic cord disease, if there is any doubt of the diagnosis, if there is only a suspicion of tumor, in the writer's opinion, operation should be performed. Naturally, where the signs clearly indicate a condition of organic cord disease, and not tumor, operation is not to be thought of. With its improved technique, the risk of laminectomy is comparatively slight. And it is far more preferable, in doubtful cases, to operate and find in some of the patients a condition of organic cord disease which will not be helped by the operation, than it is not to operate, and allow a tumor to remain with sure progression to total disability of the patient. And in the writer's experience, the proportion of tumors found in these doubtful cases is not so small as is generally supposed.

Intradural Tumor.—Intradural tumor, or tumor within the cord substance itself, is not as rare as was formerly supposed. Of all tumors of the spinal cord and its membranes, one in four is intradural. They are almost always found in the upper portions of the cord, in the cervical or upper thoracic segments. Many of these tumors are infiltrating in character, invading the cord substance in their advance, and tending to blend with it, but at times are surrounded by an area of softening of the cord substance. They usually grow in an upward and downward direction rather than transversely and often attain quite great length. Occasionally, however, intradural tumors are encapsulated and this type of tumor may extend its growth transversely, giving rise to cord signs that make it impossible to distinguish it from extra-cord tumor.

The signs of intradural tumor are usually well marked and definite. Pain, which is very often the first sign of extra cord tumor, is here absent or slight unless, as sometimes happens, the bulging of the cord, caused by the growing tumor, presses or drags upon a posterior nerve root.

From their position within the cord these tumors, by interference with the pyramidal tracts, give rise to motor symptoms below their level—spasticity of legs, with exaggerated knee and ankle jerks, clonus, and the Babinski sign. This by itself is not of diagnostic importance, as any lesion interfering with the pyramidal tracts will cause the same motor disturbances. Due to their location in the cervical and upper thoracic cord, by interference with the motor cells in the anterior horns of the cord, atrophy of muscle in the upper extremities is often seen, and this muscle atrophy occurs

earlier than that found, if present at all, in extra-cord tumor.

One of the early and definite signs of intradural tumor is dissociation of sensation. The main tracts for touch sense run in the posterior columns of the cord. The fibers carrying pain and thermal sense cross in the cord to the spinothalamic tracts in the anterolateral and anterior portions of the cord. So that an intradural tumor—depending on its position within the cord substance—will almost certainly give rise to dissociation of sensation. Owing to great size or rapid growth, or peculiar position, an intradural tumor may markedly impair all sensation below its level, but this is only occasionally seen.

As these tumors usually grow in an upward and downward direction, the level of motor and sensory impairment on the trunk or upper extremities may be gradually raised, but as an aid to diagnosis before operation it is a point one should not wait for, since any obstructive lesion within or without the dura may cause a damming of the spinal fluid, thus causing pressure with raising of the sensory and motor level and simulating an extension upward of an intra-cord tumor.

Examination of the spinal fluid, obtained by lumbar puncture, may be of aid to diagnosis. Fluid of a yellowish tint, and showing an increase in globulin, with few cells, points to tumor either intra- or extradural. Marked increase in the cells indicates an inflammatory process in the meninges.

Extradural Tumor.—Extradural tumor, or tumor arising within the dura, but without the cord substance, is occasionally found in the cervical and lumbar regions, but more frequently in the mid and lower thoracic region of the cord. Some few arise from the inner surface of the dura, but the great majority spring from the pia and arachnoid. They are nearly always single growths, but occasionally multiple sarcomata of the roots about the conus, or of the cauda equina itself are met with. Extradural tumors are usually localized, encapsulated growths, giving rise to cord symptoms solely by their compressive effect, but infiltrating growths, glioma or sarcoma, are occasionally encountered.

Extradural tumors are the most common of the new growths affecting the cord, their ratio, as compared to intradural tumor, being as 3 to 1, and as compared with extradural growths being as 2 to 1.

The first cord symptoms arising from the presence of an extradural tumor depend upon the location of the growth. If the tumor lies posterior to the cord, upon one side or the other of the median line, the first symptom is usually (but not always) pain. This is due to the pressure of the tumor upon the sensory nerve roots. The pain is at first slight and transitory in character, gradually becoming with the growth of the tumor more severe and persistent. As an extradural tumor extends its growth transversely, rather than in an upward and downward direction, these irritated roots later give rise to a zone of hyperesthesia in their areas of distribution, which is of marked assistance in determining the spinal level of the tumor. However, even with a tumor lying in this

position (posterior to the cord) and compressing sensory roots, there may be little or no pain. In one of the cases reported below, although at operation, two of the sensory spinal roots were found flattened to ribbons by the tumor, there had been no pain at any time.

Tumors, lying posteriorly, as they increase in size, compress the posterior columns of the cord, causing hypesthesia and even anesthesia to touch, and marked impairment of joint and muscle sense, since the fiber tracts for these senses lie in the posterior columns of the cord.

Tumors lying on the lateral surfaces of the cord usually cause first root pains and then by pressure on the spinthalamic tracts, give rise to marked impairment of pain and thermal sense of the contralateral side, as these tracts cross the cord. Lateral extramedullary tumor if placed a little more anteriorly than posteriorly, may be difficult to distinguish from intramedullary tumor for, due to its forward location, posterior root pains may be absent, and by interference with the spinthalamic tracts, carrying pain and thermal sense, marked dissociation of sensations may occur, and this latter symptom is a nearly constant one in intramedullary tumor. If the tumor is situated in front of the cord, the first sign of its presence will be paresis and paralysis of muscle groups, and from interference with the anterior horns of the cord, or the motor roots, muscle atrophy may occur.

The above relates to early signs caused by a tumor in its usual location, the thoracic region. If located in the upper or midcervical region, respiratory difficulty may be an early symptom. If the tumor is located at the first thoracic segment of the cord, the cilio-spinal center may be interfered with, causing impairment or paralysis of pupil dilatation. If placed in the lumbar region near the conus, impairment of bladder function may be an early sign.

As the tumor gradually increases in size, whatever its position, whether posterior, lateral, or anterior to the cord, all the cord tracts begin to show the effects of the compression. The zone of hyperesthesia, marking the tumor level, is sharpened, and the areas of hypesthesia below the lesion broadened and deepened to anesthesia. The pyramidal tracts show the effects of the compression with increasing spasticity, exaggerated reflexes, clonus and Babinski sign, paresis of muscle groups gradually increasing to paralysis. There is impairment of bladder and rectal function gradually becoming more marked. With later and more severe compression the early sign of tumor presence, root pains, is apt to lessen and disappear.

Extradural Tumor.—Extradural tumor, or tumors situated outside the dura, in the spinal canal, are quite commonly found. As compared with extramedullary growths, their proportion is as 1 to 2. Unfortunately, the majority of extradural growths are malignant.

Extradural tumor of the spinal canal springing from the soft parts is usually a sarcoma or fibroma. Sarcoma is the more frequent, arising from the outer surface of the dura, or from the periosteum. Owing to the indefiniteness of the symptoms it causes sarcoma is apt to attain quite large size before operation, and frequently causes absorption

of bone that can be detected by the x-rays. If sarcoma is situated lateral or anterior to the cord, the symptoms that arise may closely simulate multiple sclerosis with its remissions and exacerbations, and it is quite frequently mistaken for that disease, for pain may be absent even if the sensory roots are compressed (Case 1).

Fibroma of the spinal canal is small and slow growing and causes but few and indefinite symptoms for a long time. Little or no erosion of bone accompanies its growth.

Benign tumors of the spinal column, by their position, may affect the cord or spinal roots. Chondromata, fibromata, exostoses (as in a patient reported in the *American Journal of the Medical Sciences*, September, 1919, clviii, 3, page 335) may occasionally be found, but benign tumors of the vertebræ are extremely rare.

Carcinoma, which attacks the bodies of the vertebra, usually in the thoracic region, later affects the cord and roots by compression. It is never primary in the vertebral bodies, but is a metastasis from cancer elsewhere, usually the breast, and hence carcinoma of the spine is more common in women. From its position in the vertebral bodies as it extends its growth, it compresses the spinal roots first, and therefore, severe pain is usually the first and only cord symptom. Later it attacks and compresses the cord, with fairly rapid development of paralyses, anesthesia and loss of sphincteric control. The pain is more severe than that seen in other spinal tumors and there is marked tenderness to pressure over the affected vertebræ.

Sarcoma of the vertebræ, usually found under middle age, may be a primary growth, or secondary to sarcoma elsewhere. In contradistinction to carcinoma, sarcoma arises posterior to the cord in the arches of the vertebræ. Due to its position root pains are not an early sign but it gives rise to a protrusion over the spine that can often be seen and palpated. As it extends its growth, it affects the cord by compression and the signs of cord involvement, paralyses, anesthetics, and sphincteric loss, are rapid in development.

Diagnosis and Treatment.—Although from what has been said above, the signs of tumor of the cord and its membranes seem to be clear cut and well defined, such is by no means always the case. Many atypical cases are met with. Many of these new growths arise and pursue their course in an unobtrusive manner, giving rise to but few signs and these vague and ill-defined. As in tumor of the brain, the early signs and symptoms are of great importance. The early signs may be the chief means of differentiating tumor from organic cord disease, as seen in the case of the second patient reported. Later in its course tumor may closely simulate organic disease.

Root pains and impairment of sensation, areas of hypesthesia below the lesion, are if present the most important early diagnostic sign of tumor.

Other early signs may be present, depending on the location of the lesion. If in upper cervical region, disturbance of respiration; at the cervico-thoracic junction, impairment of the cilio-spinal center; and if located near the conus, early involvement of the bladder and rectal sphincters.

With increase in size of the tumor, further signs of cord involvement appear. Impairment of sensation becomes more marked, with perhaps the establishing of a zone of hyperesthesia at the upper margin of sensory impairment. This area of hyperesthesia, if present, makes a diagnosis of tumor almost certain. Spasticity, or weakness of one or both extremities, is found with alteration of the reflexes.

Lumbar puncture may be an important aid in the diagnosis, and should always be done. Syphilis of the cord and the membranes may be confirmed or excluded by this means, and a yellowish tint to the fluid, and increased globulin content strengthens the diagnosis of tumor. When tumor is suspected skiagraphs of the spine should always be taken. Both antero-posterior and oblique views should be made, for skiagraphs of the spine are difficult to "read" and even large erosions of bone may escape detection. The x -rays will disclose carcinoma of the vertebral bodies and frequently sarcoma of the canal, if the arches and laminae are eroded. An occasional chondroma may be detected by this means. The x -rays are of no assistance in intradural growths.

Organic cord diseases most often confused with tumor are multiple sclerosis and syringomyelia. An atypical multiple sclerosis with collection of fluid, localized in the thoracic region, will give an almost exact picture of tumor. Quite a few cases of multiple sclerosis have been operated upon for tumor. However, as it has been found that many cases of this type of sclerosis are benefited by laminectomy, the mistake in diagnosis is not extremely serious. And tumor, in its turn, may give rise to symptoms closely approximating multiple sclerosis, as in the first of the patients reported here.

Syringomyelia is most often confused with intramedullary tumor. Their usual locations are the same—the cervical and upper thoracic cord, and they are both lesions within the cord substance. Dissociation of sensation is common to both. Pain is absent in syringomyelia, often absent or slight in intramedullary tumor. Beyond the fact that syringomyelia usually involves more segments of the cord, and that joint changes and other trophic disturbances are common in syringomyelia, it is often impossible to make a diagnosis. Where the slightest doubt exists operation is indicated.

After deciding that the case is one of tumor, with carcinoma and sarcoma of the vertebrae excluded by the x -rays and lues excluded by lumbar puncture, the next step is the determining at what segment of the cord the tumor lies. While the motor disturbances are helpful in making a diagnosis, especially where the tumor is so situated as to cause the disappearance of isolated reflexes, such as the knee jerk, with preservation or exaggeration of nearby reflexes, yet the main reliance is placed on determining the limits of sensory impairment. This requires careful, repeated examinations. One should not make a diagnosis of a tumor-level on a single examination. Sensory examination requires the close cooperation of the patient and naturally this cooperation is not always all one could desire, and the sensory limits may apparently vary from day to day. However, by careful, repeated exami-

nations, one can nearly always locate the growth within a margin of one or two segments and very often locate not only its exact level but also its position in relation to the cord.

When the diagnosis of cord tumor is made and its level ascertained, the only treatment is operation. Naturally it is important, and almost inevitable for the sake of diagnosis and prognosis, and for the broadening of our knowledge of the signs and behavior of these growths, to attempt to determine prior to operation whether the tumor be extradural, intradural or intramedullary, but from the standpoint of treatment this is not very important. All tumors of the cord and its membranes must be operated upon. The only exceptions are carcinoma and sarcoma of the vertebrae and even in these conditions posterior sensory root section or cutting of the antero-lateral cord tracts (carrying pain and thermal sense) must occasionally be done as a palliative operation for the relief of pain. A description of the technique of laminectomy has been given in a previous article and will not be included here.

After the spinal canal has been opened by laminectomy, if the growth is found to be a removable extradural tumor, it can be rather readily removed from its bed, and peeled off the dura by blunt dissection, care being taken to avoid injuring the adjacent nerve roots. Exostoses require rongeurs and chondromata the sharp spoon. With the dura intact the cord will submit without injury to quite rough handling, but this should never be done unnecessarily. After the removal of an extradural tumor if pulsation returns along the portion of compressed cord, it is not necessary to open the dura, unless for inspection, and it should be reclosed.

If the tumor lies intradurally and its level has been correctly diagnosed, it will usually disclose its presence when the bony canal has been opened, by a bulging and sometimes a discoloration of the dural sac. When the bulging, or discoloration is absent in the field of operation, a probe should be passed upward and downward in the spinal canal for several inches before the dura is opened. Bulging of the dural sac caused by a tumor located beyond the field of operation may be detected by this means. When the dura is opened and no tumor is found, a similar, careful exploration by the probe along the posterior and anterior surfaces of the cord within the dura may disclose the tumor. Also, dilatation of the posterior spinal veins indicates an obstructive lesion above the field of operation and the tumor may be located by this means. When the growth is located and exposed, if it is an extramedullary tumor and lies in its usual position posterior to the cord, its removal is a comparatively simple matter; if it lies lateral, or anterior to the cord, its removal will be more difficult, and requires the greatest care to avoid injury to the cord. The cord substance itself should never be touched or handled. The operator must constantly keep in mind that he is not operating for the tumor, but for the sake of the cord. If the tumor is crossed by a sensory root, no attempt should be made to slide or pull the tumor from under it. This would certainly injure many cord fibers. Rather cut the root. If the tumor is closely adherent to the cord

surface, it is safer to incise the membranes over it, and attempt its removal a week or ten days later when it may be found to have partially or completely freed itself.

If the tumor is an intramedullary one it reveals its presence by a bulging, more or less marked, of the cord substance. To attempt its removal by incision and enucleation would result in as much, if not more, damage to the cord substance than the tumor itself would cause. The safer procedure is to make a longitudinal incision with a fine knife, in the posterior columns of the cord near the median line, down to the tumor, and allow the pressure within the cord to force the tumor to the surface. This will require a week or ten days to accomplish and the tumor, unless it be of the infiltrating variety, may be removed at the second operation.

The following two cases are interesting as illustrating how tumor at times may simulate organic disease, and the amount of compression the cord can successfully withstand if gradually applied.

CASE I.—C. R., aged 28. Always a healthy but quite "nervous" girl. In the summer of 1918 while nursing her mother who was dying of cancer, and taking care of the rest of the family, and much worried, she noticed transitory attacks of trembling and weakness of left leg. This weakness gradually grew worse and a few months later appeared in the right leg, and later, spasticity of both legs. When I first saw her in June, 1919, her condition was as follows: An anemic, emotional girl with spastic para-paresis of lower extremities, reflexes exaggerated, double slight ankle clonus more marked in the left side, double Babinski. Upper abdominal reflexes present and equal, lower right abdominal reflex feeble and the left absent. Tremor of hands intentional in type, and lateral nystagmoid twitchings present in both eyes. Optic discs were normal. There were no subjective or objective sensory disturbances and she had had no pain at any time. No sphincter impairment, no tenderness over spine. A diagnosis of multiple sclerosis was made and the same diagnosis had been made by others at previous examination. Lumbar puncture a month later gave normal pressure finding (spinal fluid manometer), a normal clear fluid and a negative Wassermann. Blood Wassermann also negative. Patient was lost sight of until January, 1920. At this time her condition had markedly changed. From August, 1919, on, the spastic condition had become gradually aggravated so that by October she could lift neither leg from the bed. In November, she had first noticed impairment of sensation. The condition in January was as follows: complete spastic paralysis of both legs to hips; motor power entirely abolished except in two toes of the left foot. There were occasional spasmodic contractions in the legs. There was hypesthesia to all forms of sensation below the umbilicus. Touch sense was better maintained than pain and thermal sense. No tenderness over the spine and no disturbance of the sphincters. Tremors of the hands had disappeared and the nystagmoid twitchings were found only when she was fatigued by repeated examinations. Lumbar puncture at this time showed four cells and slight increase in globulin. Diagnosis of cord tumor was made near the tenth thoracic segment at the level of the seventh thoracic vertebra. X-rays revealed nothing. Laminectomy was done February 5, 1920, removing the laminae of the sixth, seventh, and eighth thoracic vertebrae. A large extradural tumor (size of small hen's egg) was found occupying the left portion of spinal canal markedly compressing the cord. The tumor was firm to touch and encapsulated except at its posterior pole. It was adherent to the dura, but was rather readily peeled off as it also was from its bed in the spinal canal. Quite marked erosions of the transverse arches and the laminae of the seventh and eighth vertebrae had occurred. The foramina of the seventh and eighth left posterior spinal roots were eroded and the roots found flattened to ribbons, and

yet there had been no root pain at any time. With the removal of the tumor the normal pulsation returned in the portion of cord compressed and the dura was not opened. Wound sutured and a straight plaster of paris splint applied to the spine. P. O. notes:—Ten days after operation patient could flex and extend legs and thighs and could raise feet from bed. Sensory impairment improving. Left hospital twenty-five days after operation. At this time could walk by holding to objects or placing hand against the wall; sensation was practically normal. Because of the large amount of bone erosion she wore a spinal brace for three months. Two months after operation she did light housework and could walk several blocks without fatigue. Improvement was gradual and steady so that when seen five months after operation she walked normally with no trace of spasticity, had been dancing, did all her housework, and had resumed her normal life. The knee jerks were still plus with double Babinski. Ten months after operation she was well and had no complaints.

The tumor was reported by one laboratory to be an atypical spindle-cell sarcoma with many giant cells, and many unidentified crystals at the posterior pole where the capsule was missing. It had outgrown its blood supply, was broken down and soft in the center and sectioned poorly. By another laboratory, it was reported as an indefinite benign growth with no signs of malignancy. There have been no signs of return of the tumor 9 months after removal. As there were no signs of loose tissue masses seen at operation, it is probable that the gap in the tumor capsule at its posterior pole was made by the rongeurs in removing the laminae of the eighth vertebra, into which the tumor had eroded deeply. If so the probability is strong that there will be no return, even if it be sarcoma.

The interesting features of this case are the quick recovery of function after operation and the exact picture it presented (except for absence of optic disc pallor) in its early stages of multiple sclerosis. It is difficult to explain the absence of root pain in view of the operative findings.

CASE II.—F. M., male, 16 years. During the summer of 1916, when patient was 12 years old, he was struck by a street car, receiving general and severe bruises, but does not know if his back was hurt; says there was no paralysis of legs. Was in bed at home for six weeks, and fully recovered by that time. Three years later, in the fall of 1919, he had occasional shooting pains in back and legs with slight tenderness of the back in the lower thoracic region. Pain in back was increased by stooping. These transient pains continued until March 1, 1920, at which time he had "pins and needles" sensations in legs, with weakness in both knees, so that occasionally a leg would give way under him while walking. This weakness rapidly increased so that in two weeks he was unable to walk. The following week he complained of numbness in both legs, and some difficulty in emptying the bladder. His condition was diagnosed as either polyneuritis or a beginning myelitis. I first saw him March 23, 1920. At this time there was a flaccid paralysis of both legs to the groin, with marked wasting and atrophy of the muscles. Knee and ankle jerks absent. Motor power completely abolished except for the toes on the left foot. Tactile sense was preserved, but there was hypesthesia to pain and temperature found in both legs. He complained of severe pains in the back and tenderness to pressure was found over the spine from the eleventh thoracic to second lumbar vertebra. Muscles of the legs were markedly sensitive to pressure. Sphincter disturbance was present but not marked. X-rays revealed nothing abnormal in the spine. Although the signs indicated a possible polyneuritis or a myelitis, yet because of the history of indefinite root pains, six months previously, and the presence of tenderness over the spine, tumor was suspected near the

conus, affecting the lumbar segments of the cord and an exploratory laminectomy advised. Operation was done March 29, 1920. When the laminae of the twelfth dorsal and first lumbar vertebrae were removed a bulging dark red mass was revealed entirely filling the spinal canal. Careful search failed to locate the cord in this mass. Removal of one spinous process and laminae above, disclosed a normal pulsating dura and removal of the laminae below disclosed a bluish congested dura without pulsation. Blunt dissection removed the larger part of the dark red mass, which came away in friable, laminated sections, apparently organizing blood clot. The greater part of the mass lay anterior to the cord. Beneath the dark red mass was found a band of dense yellowish fibrous tissue one inch in breadth encircling the dura and closely adherent to it. This was divided and dissected from the dura with great difficulty. With division of the constricting band normal pulsation appeared in the dural sac below the lesion. Dura was not opened and the wound closed with one drain down to the tumor site.

Postoperation Notes: Profuse grumous bloody discharge for two days, and then a low grade suppuration occurred, speedily cleared up by use of Dakin's solution. With this exception the convalescence was uneventful. The pain in back disappeared with operation and eight days later the patient could flex and extend the left foot, and move toes of the right foot, and a week later could flex left knee and move right foot. Sphincter impairment had disappeared. Improvement from this time on was gradual and steady, so that one month after operation sensation was normal and he could walk when held on one side. Left leg much stronger than the right, knee and ankle jerks still absent. Three months after operation he could walk up and down stairs and across a room unaided. Muscles had rounded out and the left leg was almost normal in size and strength. Right leg still weak but improving; left knee and ankle jerk were feebly present; the right absent. He was steadily improving when seen eight months after operation.

The pathological diagnosis of the tumor was that it was an endothelial angioma springing from the connective tissue. Doubt was expressed as to malignancy.

Tumors of the spinal cord that manifest the typical signs are rather easy to diagnose. The important point to bear in mind is that many, possibly one-half, of these tumors are atypical and give rise to symptoms that are either slight and indefinite or that simulate organic disease to a remarkable degree. In any cord lesion one should be on the alert for signs of tumor presence. And when signs of tumor are found, even though they be slight and indefinite, if persistent, an exploratory laminectomy is not only justifiable but necessary.

107 EAST THIRTY-NINTH STREET.

A CONCEPT OF X-RAY PATHOLOGY.

III. PLEUROPATHY.

By A. J. PACINI, M.D.

WASHINGTON, D. C.

CHIEF LABORATORY AND X-RAY SECTION, HOSPITAL DIVISION,
U. S. PUBLIC HEALTH SERVICE.

THE diseases of the pleura with which the x-rayist is commonly concerned may be divided into four groups: (1) Inflammation; (2) Circulatory Disorders; (3) Air Invasion of the Pleural Sack; (4) Tumors.

Whatever the anatomical pathology producing pleural inflammation, the x-ray pathology resolves itself into two factors: a thickening of the pleural surface due to a connective tissue proliferation, or a filling of the pleural cavity with the fluid products of infection activity. These evidences may occur singly or conjointly.

PLEURITIS.—Simple inflammations of the pleura may be due chiefly to pyogenic organisms; in other cases the infection may be specific, as tuberculous or luetic. In acute pleuritis the exudate may consist practically entirely of fibrin, when the condition is known clinically as dry pleurisy. The coating of the fibrin over the infected pleural layer will appear on the plate as a radiolucent or radiopaque mantle. Normally, the serous pleura is radioparent and does not register on the plate; but when attacked by pathology, the pleura become radiolucent or radiopaque. Instead of being composed entirely of fibrin, pleural exudate incited by infection may be fluid. When fluid, pleural effusion may be serous, serofibrinous, hemorrhagic, or purulent. In the order of their radiability, these effusions are radiolucent when serous, radiopaque when serofibrinous, still more radiopaque when hemorrhagic, and of maximum radiopacity when purulent.

Dry Pleurisy.—Dry pleurisy is usually difficult to diagnose from x-ray evidence alone. Usually on the affected side, at the beginning of the infection, there can be seen, when viewed fluoroscopically, a paresis of the diaphragm.

Since dry pleurisy is most often associated with a tuberculous infection, a locus of tuberculous activity should be sought in the lung on the affected side. The actual excursion of the diaphragm is generally lessened in acute pleurisy; so that a double exposure on a single plate made at the end of inspiration and immediately at the end of expiration, will show on the affected side a lessened diaphragmatic journey compared to the normal side.

Pleurisy with Effusion.—The majority of serous pleurisies have as a basis a tuberculous origin; so that in serous pleurisy, as in dry pleurisy, signs of tuberculous infection should be sought in the lung areas. In a limited number of cases the original tuberculous focus may have become extinct in the lung and may reside latent either in the hilus glands or in the pleura. Active pleural tuberculosis leading to pleuritic effusion is not uncommon as a terminal complication in cases of chronic cardiopathy. As the fluid forms, it collects in the most dependent parts of the thoracic cavity. On the x-ray plate these are the costophrenic sulci. As the fluid collects in the costophrenic sulci, the normal lung structure is displaced by the invading serum. The fluid, being radiolucent, occasions a shadow to be cast in the sulcus with the obliteration of the normal outline. Mobile serous fluid, in the absence of a concomitant fibrinous exudate, causes a horizontal fluid level to appear when exposure is made with the patient upright. As the pleural cavity becomes more and more filled with effusion, an even obliteration by the radiolucent shadow proceeds, the level remaining horizontal until the upper third of the thoracic field is reached.

If more fluid is poured into the pleural cavity after a hemithorax is filled to its upper third, the lung, which is fixed at its central portion, cannot yield at the root, but can only yield at the peripheral margin; so that the rising fluid level no longer remains horizontal, but assumes an inclination, being lower at the root of the lung and higher at the margin. This is the line of Damoiseau described by Barjon. The effusion may continue until the entire thoracic area on one side is obliterated.

The x-ray pathology of pleurisy with serous, serofibrinous and hemorrhagic effusion is practically identical and is characterized by a radiolucency that fills first the costophrenic sulcuses on the affected side, maintains a horizontal level, obliterates the cardiophrenic sulcus, continues to rise with a horizontal level until the root of the lung is reached, then rises with its level inclined, the inclination becoming more acute as the fluid increases until finally the entire hemithorax is evenly obliterated by the opacification; and incident to the pressure exerted by this volume of fluid, the mediastinal structures and the cardiovascular stripe are displaced to the opposite or unaffected side.

Pleurisy with Purulent Effusion.—When the pleuritic effusion is purulent, the sulci are the first to disappear as in ordinary effusion. The shadow caused by pleuritic purulent effusion are denser or more radiopaque than those of other effusions. This difference in radiopacity is purely relative and can seldom be used as a means for distinguishing from the x-ray evidence between the pathological character of the various effusions in pleurisy excepting when the purulent effusion attains a combined fibroseropurulent property. In this case the fibrinous exudate attaches itself to the pleural parietes, and this, together with the less mobile character of the effusion, precludes the assumption of a clearly defined fluid level. In some cases, then, a dense radiopacity obliterating a dependent portion of a thoracic field with an irregular upper boundary, differing from a mobile fluid level, it is possible to predicate the fibropurulent character of the pleuritic fluid.

The lung area on the healthy side may be less clear than normal if the effusion of the other side be large. This is subscribed to partly on account of the lung compression, and partly because of a contemporaneous hyperemia. When the effusion is small in amount the lung on the affected side, owing to a vicarious emphysema, may be unusually clear.

Empyema.—Empyema, or purulent pleurisy, may involve a pleural cavity as above described or it may be encapsulated or interlobar. The x-ray diagnosis rests in a radiopaque hanging shadow. It is characteristic and is seldom mistaken for any other condition. Following a pneumonia, empyema should always be suspected in cases of encapsulated fluid inclusions in the chest.

Pleural Thickening.—This is a chronic inflammation of the pleura with the formation of new fibrous tissue between the layers. There may be an obliteration of the entire pleural cavity on one side with an incident reaction of the bony framework, or a partial yet extensive obliteration, or only circumscribed adhesions. The thickened pleura may become so radiopaque as to make it indistinguishable, from x-ray evidence alone, from the opacification due to effusion.

If the thickening involves one surface, such as the anterior surface, an x-ray differentiation between chronic pleuritis and pleuritic effusion can be effected as follows:

Two exposures are made, one in dorsoventral view, the second ventrodorsal. If the radiopacity affects one surface as the result of a pleuritis, it will be relatively more radiopaque in one or the other of the two exposures; the greatest radiopac-

ity appearing in the exposure made when the thickened pleura more closely approximates the x-ray plate. If the radiopacity is due to a pleuritic effusion, the intensity of radiopacity will remain equal in both views, ventrodorsal and dorsoventral.

Thickened pleura sometimes become calcified and then show great radiopacity characterized by circular or radiating shadows.

Adhesions to the diaphragm are readily discerned by the x-ray. The diaphragmatic cupola is suspended by an adhesion and is remarkably illustrated, particularly if the exposure is made on deep inspiration.

Interlobar pleural scleritis may appear as a radiopaque linear marking running transversely across a lung area in the position of the interlobar septum. It may represent a part of a moderate general pleuritis, only the interlobar scleritis showing because of the radiopacity incident to the pleural surface being rayed endwise. As an analogy, a sheet of glass viewed through its thinness is transparent; but when viewed through its edge is translucent if not opaque. So with a pleural surface; when moderately inflamed, rayed through its thinness the inflammatory reaction may be insufficient to register any change in radiability. Rayed through its edge, as in a septum, the combined thickness may cause a radiopacity.

Circulatory Disturbances Involving the Pleura.—

Three important circulatory disturbances may invade the pleural cavity. These are hydrothorax, hemothorax and chylothorax. Hydrothorax is a transudate into the pleural cavity and is a non-inflammatory effusion. Its x-ray pathology, however, is in every way similar to a pleuritic serous effusion and consists of an obfuscating radiopacity of an extent proportional to the amount of transudate present. The following x-ray test is sometimes fruitful distinguishing between a transudate and an exudate. Potassium iodide, or better sodium iodide, when given by mouth, usually appears in a transudate, but fails to appear in an exudate. A transudate containing small amounts of sodium or potassium iodide becomes more radiopaque than when these salts are not present. In the x-ray test, therefore, if an area of effusion becomes increasingly radiopaque following iodide administration, the evidence points to a transudate instead of to an exudate.

Hemothorax and chylothorax cannot be divided on the x-ray plate from hydrothorax. The distinction must be made in the laboratory and from clinical symptoms.

Pneumothorax.—Pneumothorax may occur pure, only gas filling the pleural cavity, or complicated with the presence of serous or purulent exudate. When complicated, seropneumothorax and pyopneumothorax cannot be distinguished one from the other. They can be differentiated from other pleural effusions if the pneumothorax is complete; in which case the area overlying the effusion is void of lung tissue.

Pneumothorax, considered from its etiology, is frequently associated with tuberculosis. It has been estimated that 30 per cent. of pneumothoraces are associated with tuberculosis of the lungs. It is not necessary, from the x-ray standpoint, to need additional x-ray pathological evidence other than that

caused by pneumothorax in order to recognize air in the pleural cavity. The collapse of the lung induced by pneumothorax removes all structure from the lung area and leaves a homogeneous radioparent field. The condition is instantly recognized.

Tumors of the Pleura.—Primary tumors of the pleura are rare. Most often, pleural tumors are metastatic.

Malignant growths of the pleura are generally accompanied with pleural effusions. It is difficult to distinguish, at times, between tumors of the pleura and those of the lung.

DIAPHRAGM.—On the x-ray plate the diaphragm appears as a double dome, the convexity toward the thoracic cavity. On the right side the dome is higher than on the left, owing to the liver surface. The costophrenic spaces are important loci for the detection of certain forms of x-ray pathology. These have already been considered in the discussion of pleural effusion.

Under fluoroscopy, a relative paresis of one or both cupolas of the diaphragm may be observed; and in a less satisfactory manner inhibited diaphragmatic excursion can be demonstrated on the plate by double exposures, one at inspiration, and the second at expiration.

The diaphragm expands the lower lobes of both lungs. Paralysis of the diaphragm may cause, therefore, collapse of this portion of the lungs. This collapse may in some cases amount to a lobar atelectasis.

Diaphragmatic Hernia.—This may be congenital or acquired. In extreme defect, the congenital type is incompatible with life. The acquired type usually follows some form of trauma.

Evisceration.—When the abdominal viscera, particularly intestines, by trauma are projected through a rent in the diaphragm, the condition is recognized as evisceration. Its x-ray pathology is best studied after an opaque feeding and is made usually in connection with gastrointestinal examinations. It rests with the anatomical demonstration of the abdominal contents projecting through the diaphragm. In the case of the intestine, which is always to some extent metoric, protruding gut can be visualized in the lung area by reason of the outline owing to the included gas.

Eventration.—In eventration, a relatively rare condition, generally one-half of the diaphragm is exceedingly expanded upward, allowing the abdominal contents to encroach upon but not into the lung area. From the x-ray pathology eventration is distinguished from evisceration by the fact that in eventration the diaphragmatic arch, although high in the lung area, is regular and unbroken.

Diaphragmitis.—Primary inflammation of the diaphragm is comparatively rare; but secondary diaphragmitis occurs more frequently than is generally taught. It follows as a sequel or may occur as a complication to an inflammatory condition involving either the thoracic or the abdominal viscera. Usually the thoracic viscera are responsible for the diaphragmitis. The x-ray pathology of diaphragmitis is limited to a paresis, sometimes paralysis of the muscle. An abnormally low position of the diaphragm leaf is sometimes significant of diaphragmitis.

Subdiaphragmatic Abscess.—Two types of sub-

diaphragmatic abscess are clinically recognized: (1) Simple diaphragmatic abscess; and (2) a gas containing abscess, sometimes referred to as subdiaphragmatic pyopneumothorax (Leyden).

With relatively few exceptions the primary focus of infection is in the abdomen, and it is only occasionally that the abscess originates above the diaphragm. In the simple diaphragmatic abscess the x-ray pathology consists of an upward displacement of the diaphragmatic dome on the affected side. The relative height between the two domes on the right and on the left is of critical importance in the study of diaphragmatic lesions; and in subdiaphragmatic abscess, as the purulent exudate accumulates, the diaphragmatic cupola rises. Obviously, the x-ray pathology in incipient cases is identical to that of far advanced cases; the only difference resting with the extent of diaphragmatic elevation.

In the gas containing abscess the x-ray pathology is similar to the simple abscess in that the diaphragm on the affected side assumes a level higher than normal; but the pathology is more distinctive by reason of the gaseous inclusion in the products that elevate the diaphragmatic leaf.

It is difficult in all cases to be sure from the x-ray pathology that the elevation of the right diaphragmatic cupola is the result of subphrenic purulency, and not the result of a tumor or abscess of the liver itself.

MEDIASTINUM.—G. von Bergmann presents the following convenient classification, clinically, of diseases of the mediastinum:

CLASSIFICATION OF DISEASES OF THE MEDIASTINUM.

1. Displacement of the mediastinum through pressure or traction from the outside (disturbances of the septal function). (a) Total displacements; (b) Partial displacements.
2. Space-occupying processes in the mediastinum (disturbances of the channels of communication in the mediastinum). (a) Small masses; (b) Large masses.
3. Diseases involving the lymph spaces of the mediastinum (disturbances of the lymphatic function). (a) Acute mediastinitis; (b) Chronic mediastinitis; (c) Mediastinal hemorrhage; (d) Mediastinal emphysema.

The x-ray pathology of mediastinal diseases can be similarly classified into: (1) Changes due to displacement; (2) obliteration of mediastinal space; (3) hypertrophy involvement of mediastinal lymph structures.

Mediastinal displacements are due to secondary pathology and have been in part considered under pleural effusion, and will be further considered under cardiovascular involvements affecting the mediastinal site.

Occlusion of mediastinal space may be due to tumors, hemorrhages, abscesses, mediastinal pneumothorax, mediastinal emphysema, aneurysms, esophageal diverticula, enlarged lymph glands.

The x-ray pathology of mediastinal occluding lesions is simply that of a radiopaque area present in the mediastinal space. The oblique and sagittal exposures, in addition to the dorsoventral, should in all cases be included better to localize the origin of mass occasioning radiopacity. Small mediastinal radiopacity may be due to glands hypertrophied through invasion by tuberculosis or by syphilis; or to glands enlarged as the result of Hodgkin's disease or leukemic affection; to a stasis lymphadenitis;

or to metastatic tumors. There is no positive x-ray differentiation of these small masses from the radiopacity cast by their shadow on the x-ray plate. Their position in the mediastinum and the simultaneous presence of other x-ray signs pointing to the etiology may, at times, indicate the exact character of the pathology.

Large tumefactions of the mediastinum may include enlarged thymus, Hodgkin's disease, lymphosarcoma, leukemic and aleukemic lymphadenosis, or metastatic sarcoma or carcinoma.

Enlarged Thymus.—Thymus enlargement occurs for the most part in infants and children; but it may occasionally be found in adults. The x-ray pathology consists in the presence of a radiopaque area occurring apron-like in the upper lung areas. The apron assumes a triangular shape, often with the base above and the apex pointing downward. Occasionally it may occur in the reverse form; the apex pointing upward and the base below. When in this form the radiopacity due to the thymus generally overlays the heart shadow, the base of the radiopacity resting on the base of the heart. An x-ray distinctive feature of radiopacity due to a thymus shadow is the fraying of the periphery of the shadow. This is due to the unevenness of the surface of an enlarged thymus. Another distinctive characteristic sometimes pertinent to the radiopacity of a thymus shadow is that of the equal distribution in the amount of radiopacity on each side of the midthorax line.

Large mediastinal masses casting radiopaque areas may be due to Hodgkin's disease. The x-ray pathology is that of a mediastinal tumor affecting the lymph nodes. The diagnosis cannot be made from the x-ray plate alone. Enlarged lymph nodes elsewhere in the body, and the blood picture must be used to assist in arriving at the proper diagnosis.

Intrathoracic Tumors.—Among the benign tumors met in the mediastinum may be mentioned the following: Fibroma, lipoma, chondroma, myoma, simple cyst, dermoid cyst, and teratoma. Of these, dermoid cysts are the most common.

Tumors involving the mediastinum are more frequently malignant than benign.

In all varieties of new growths a dense shadow extends outward from the mediastinum, usually on both sides. The radiopacity of this shadow blends with the radiopaque heart silhouette. Under fluoroscopy the radiopacity due to the heart can be distinguished from a radiopacity due to a mediastinal tumor.

Says Barker on the topic of roentgenoscopy of the mediastinum:

In the diagnosis of large tumors of the mediastinum, several types can be distinguished in x-ray pictures; thus, if in the roentgenogram one sees a shadow projecting like a mole-hill at the junction between the cardiovascular stripe and the clear lung area, its surface being either hemispherical, with the center of the sphere lying at the root of the lung, or uneven, with jagged contours, one can be sure that he is dealing with a hilus tumor. Such a mediastinal tumor at the hilus has to be distinguished from a tumor of the lung on the one hand and from an aortic aneurysm on the other.

In large tumors of the mediastinum due to Hodgkin's disease, one sees a mass either to the right or to the left of the sternum, or on both sides, usually feebly convex, and extending all the way from the clavicle down to the heart. When the tumor projects to the left side, the differential diagnosis from aortic

aneurysm may be difficult, though the pulsation in aneurysm, visible on roentgenoscopy, may help. Tumors of the lung itself are usually easily distinguishable from mediastinal tumors proper, though in some cases the roentgenogram leaves one uncertain. Thus, a tumor arising in a lymph gland at the hilus of the lung, or in the bronchial mucous membrane near the hilus, usually gives rise to a shadow extending out into the lung but more or less separable from the cardiovascular stripe; and when the shadow becomes confused with the cardiovascular stripe, the predominant involvement of one lobe of a lung may give one the clew to a pulmonary rather than a mediastinal origin of the mass (v. Bergmann).

In judging of the nature of mediastinal tumors, one should pay attention not only to the appearance of the main shadow, but also to certain additional points: (1) the presence or absence of a pleural effusion, (2) the presence or absence of darkening of one whole lung area (bronchiectasis), (3) the involvement of non-involvement of the arch of the aorta. It is also important to make out, if possible, whether we are dealing with a compact uniform mass or with a composite mass made up of several parts, as in lymph-gland enlargement (bronchial-gland tuberculosis, Hodgkin's disease).

Mediastinitis.—Acute and chronic mediastinitis are clinical rather than x-ray entities. When the inflammatory process is such as to occasion a deepening of the hilus shadow, a mediastinitis might be suspected providing the clinical indications point to the possibility of infection.

THE CALORIC VALUATION OF FOOD.

By MAX MALKIN, M.D.,

CHICAGO, ILL.

THE energy value of food may be determined by burning samples in a bomb calorimeter in an atmosphere of O to secure ready and complete combustion. The heat given off passes through the walls of the bomb and is taken up by a known volume of H₂O at a known temperature."—International Cyclopedica.

"By a caloric is meant the quantity of heat necessary to raise 1 gram of H₂O 1 deg. (Centigrade) in temperature."—Bassler.

From the above quotations one can readily see how the calorimetric deductions have been ascertained, and in the following dissertation we will disclose the fallacy and show that while calorimetric estimates in mechanics may be correct they are entirely inadequate in determining the energy quotient in food products. We take for a comparative study the following foods which are in daily use: fresh beef, veal, fish, vegetables, bread:

TABLE OF FOOD VALUES (BASSLER).

	Refus ¹	H ₂ O.	Protein	Fat	Carbo- hydrate	Ash	Food value per pound.
	%	%	%	%	%	%	Calories.
Beef	14.3	40.6	12.5	31.9		.7	1580
Veal	21.4	53.1	15.1	9.6		.8	685
Fish	54.8	34.6	9.3	.8		.5	205
Vegetables (four)		13.8	7.9	1.4	76.4	.5	1625
Bread		35.4	9.5	1.2	52.8	1.1	1205
Sugar (granulated)					82.8		1540
Honey					75.1		1395
Vegetables (lima Beans)		13.2	22.3	1.8	59.1	3.6	1590

Protein-containing food can usually be utilized for an extensive period without causing toxic cumulative effects, and it gives more energy per pound than a carbohydrate food which cannot be tolerated over an extensive period because of its toxic cumulative effects in the human system.

One can readily see from this that oats per pound do not contain the same caloric value as does a pound of steak. It is evident that enzymes and natural ferments in the protein diet can be tolerated and are really better tissue builders than the carbohydrates. There is less of the protein required to satisfy the needs of individual energy. This is not the case with carbohydrates, as they are cumulatively toxic in the system. Therefore, one can say that our dependence must be not only on the caloric value but also upon the natural composition of the food product and its ability to react on the human system. For that reason oats may have the caloric value by weight, but this caloric value lacks intensity and duration, which are of great importance for the establishment and maintenance of strength.

The following every-day home experiment will prove my deduction. In heating both water and broth separately to a boiling point, we find that it requires more energy to heat the broth than to heat the water, or in other words it takes more time to bring the broth to a boiling point. Supposing one should raise the heat of water to that of an equal quantity of broth, which would be preferable from a dietary point of view, both having the same caloric value? One can readily see that there is a difference in energy quotient.

Why is water more reliable when using it in a specific gravity test, while it is not as reliable as a calorimetric test? The water under ordinary temperature is a liquid and the molecules glide over one another and its composition remains constant. However, water brought by heat to a state of vapor loses its constancy and evaporates. While its specific gravity may remain fairly reliable in a comparative test on account of the stability of the water. The thermometric test of heat in water, owing to its lack of constancy, and owing to the fact that heat is only one element in the combustion of food, becomes fallacious. While the water has latent energy and can be utilized when heated, food has potential energy. When food is incinerated, therefore, and its calories are deduced by thermometric test, we fail to get a true value of the energy contained therein.

69TH STREET AND WENTWORTH AVENUE.

SPONTANEOUS RUPTURE OF THE UTERINE ARTERY DURING CONFINEMENT.

By JOHN C. MAJOR, M.D.,

JOLIET, ILL.

I WAS called to attend Mrs. S., Joliet, Ill., a primipara, who had been in labor two hours. I made an examination of the case and found the os uteri fully dilated and labor progressing rapidly, head in normal presentation, vagina large and roomy, and pains regular but weak. I gave 1 c.c. pituitrin, which increased the strength and frequency of the

pains. In three quarters of an hour I delivered a seven-pound girl. The after-birth soon followed, the uterus contracted down good and firm, and I left the patient feeling very comfortable. About an hour later I received a call to come at once as the patient was in severe pain. I reached the house in about fifteen minutes and found on examination a large tumor or swelling on the left side, distending the vulva, protruding about one inch externally. On introducing the index finger I found a mass filling up the entire vagina, and could just squeeze the finger in between the tumor mass and the right wall. The patient complained of severe pain and a feeling of great distention. I gave one-fourth grain of morphine to relieve pain and kept the patient perfectly quiet. The uterus was firm and contracted just as I had left it an hour previously. I used a mild antiseptic dressing externally to prevent infection. On calling the next day, I found the patient with no pain. The third, fourth, and fifth days passed without any change. On the sixth day the patient had a temperature of 102°, due to absorption of fibrin from the blood. The swelling gradually went down. On the seventh day two holes the size of a quarter dollar sloughed and large clots of blood came away, accompanied by a discharge resembling pus. On examination through the vagina on the twelfth day I found the tumor entirely gone and the patient made an uninterrupted recovery.

I have practised medicine twenty years, but have never had anything like this. The tumor could have resulted from nothing else than rupture of the uterine artery and infiltration of blood through the cellular tissues.

YOUNG BUILDING.

Medicolegal Notes.

Maintenance of Physician's Office—Restrictive Covenants.—The vendor of real estate informed the purchaser that he could maintain a physician's office on the premises, despite a covenant restricting the use of the property to residential purposes. The vendor, however, was unable to secure a modification of the restrictive covenant. It was held that the covenant constituted an incumbrance on the title and warranted the purchaser in refusing to carry out the contract of purchase.—*Bertola v. Allred*, (Cal.), 189 Pac. 489.

Death from Hemorrhages Caused by Swimming Against Current Not Result of Accident.—One insured against accident, who was apparently in good health, but who was suffering from tuberculosis, sustained a hemorrhage while swimming against a strong current, and died within a month as the result of violent and successive hemorrhages. It was held that the death did not result from "accidental means" within a certificate insuring against death from injuries received through "accidental causes."—*Olinisky v. Railway Mail Assn.*, California Supreme Court, 189 Pac. 835.

Statements to Attending Physician as Evidence.—In an action for personal injuries testimony of a medical expert on cross examination was objected to on the ground that his opinion was based, in part, on statements made to him by the plaintiff. Neither the statements nor the time and circumstances thereof were developed. On appeal the Supreme Court of Arkansas held that, without knowing what statements the plaintiff made to his attending physician during his illness, as well as the time and circumstances under which they were made, it could not determine whether such expert opinion was competent.—*Subiaco Coal Co. v. Krallman* (Ark.), 220 S. W. 664.

RECENT DEVELOPMENTS IN SYPHILOGRAPHY.

THE Syphilis Number of *La Médecine* for November, 1920, ii, 2, comprises an unusually good symposium on syphilis. Gougerot, the editor, leads off with a general summary in which he discusses treatment, iocism *vs.* dualism, nervous syphilis, and heredosyphilis. In a special article Queyrat advises high weekly doses of arsenobenzol. Sabouraud writes on his favorite subject of dentition in heredosyphilis and continues his polemic against the dentists concerning the specificity of certain dental dystrophies. Sicard discusses the treatment of nervous syphilis and asserts that very small, repeated doses of arsenobenzol are obtaining results impossible under the original methods of exhibition. Iodine is added to the arsenicals. He claims improvement in all organic syphilitic diseases of the nerve centers with the exception of general paresis; but while as a general proposition this affection is "irreducible," he has a few cases in which infinite perseverance seems to have been followed by remarkable amelioration. Milian writes of icterus following arsenobenzol and states that this manifestation indicates an hepatic relapse. In such a contingency he goes ahead with the arsenical medication. Brin gives an account of erythrodermias following the latter. These eruptions are polymorphous and seem to indicate at times hepatic insufficiency, but have more than one mechanism.

Gougerot takes up the pathogeny of the neurorecidives following the use of arsenicals. These late accidents are often a melange of toxic results from the drug and actual specific lesions. The drug has caused visceral lesions such as follow the abuse of arsenic, and the syphilis is then of a type incoercible by arsenic, and recurs despite treatment. Furthermore, syphilis may have been so modified by the action of arsenic that its individuality has suffered and it has become a hybrid affection. Pomaret writes on the elimination of arsenic. While a small fraction remains fixed in the tissues the bulk is eliminated by the intestines and kidneys. In the intravenous use most of the arsenic is quickly eliminated and chiefly by the bowel. The drug gains the intestine principally through the bile. Mercury given with arsenobenzol retards the elimi-

nation of the latter. Spillmann refers especially to the importance of early diagnosis and treatment. The subject matter is somewhat trite but the point is made that the pharmacist can cooperate by sending all suspicious cases to the practitioner without delay. It is unfortunate that the policy of the druggist in temporizing is responsible for many cases getting past the abortive period.

Lévy-Bing and Gerbay discuss conditions which permit of abortive treatment. The latter must begin before the thirty-eighth day following contamination. Tzanck writes of the treatment of the disease during the incubation period. One should not wait for the positive seroreaction. Lévy-Frankel speaks of "epidemic" accidents from novarsenobenzol which can be attributed only to poor preparations. Blechman gives his experience in treating nurslings by intravenous injections of the same medicament. He obtained good results by throwing the substance into the epicranial and jugular veins and the superior longitudinal sinus. Finally Ronchese and Bloch write respectively on the ordinary and intraspinal seroreactions. The Wassermann should be approximated in some manner to the Bordet-Gengou type. The intraspinal reaction ranks now as of the first importance and no longer as merely corroborative.

RECENT THEORIES OF HEARING.

THEORIES as to hearing have changed considerably in modern times, and even now there is no complete agreement on the subject and the explanations of Helmholtz, Wrightson, Rutherford, Meyer, and Lipp have all been criticized. The latest critical review of these theories was made by Mr. G. Wilkinson in a paper read before the Sheffield Medico-Chirurgical Society on Nov. 4, at Sheffield. Helmholtz's application of resonance to explain the analysis of sound by the cochlea was described.

The facts in support of Helmholtz's view that each of the transverse fibers of the basilar membrane has its own proper period of vibration, progressively increasing from the base to the apex of the cochlea, are as follows: (1) These fibers increase progressively in length from base to apex; (2) As Professor A. Gray has shown, the external ligament probably regulates the tension of the transverse fibers, and this ligament progressively decreases in bulk from base to apex. It is therefore probable that the tension of the transverse fibers progressive decreases. (3) The "load" on the transverse fibers, that is, the mass of the perilymph and endolymph intervening between each string and the oval and round windows progressively increases. Wilkinson in discussing this theory says that while it might be difficult to accept the view that these factors are sufficient to give the basilar membrane the amount of differentiation required for a series of resonators extending to nine octaves, in any event they would give sufficient differentiation entirely to destroy the value of the basilar membrane as a simple recorder of the movements of the stapes, as postulated by the theories of Wrightson and

Rutherford, or as a simple yielding membrane without resilience, as pictured by Ewald, Meyer, and Kuile. For such a purpose a simpler structure would answer better.

As for Wrightson's theory, Wilkinson asks, why is a large and important nerve like the auditory, with its 4,000 or more branches in the cochlea at all necessary for the performance of so simple a function? Is it to be believed that each of these 4,000 nerve twigs is carrying identically the same message to the brain at the same time? There seemed to be a fundamental misconception in all theories of analysis of sound by the brain, such as Wrightson's, Rutherford's, Meyer's and Lipp's. In the opinion of the lecturer the essential act in sound analysis is not the resolution of pressure curves into their harmonic components, but the instantaneous measurement of small intervals of time. The disintegration of one of Wrightson's sound pictures would necessitate the immediate recognition by the hearing center of differences in the phase periods amounting to one 100,000th part of a second. The measurement of time is essentially a mechanical operation. All our methods of measuring time depend on instruments giving harmonic vibrations. He contended that the theories of Ewald and Kuile do not seem to offer a satisfactory explanation of the resolution of compound into simple tones. Up to the present no satisfactory working model of the cochlea has been made. Helmholtz's theory undoubtedly gives a fuller and more comprehensive explanation of the facts of hearing than any other. The difficulty of accepting it lies in certain anatomical details of the structure of the cochlea, but if Helmholtz's theory is rejected, up to the present time no satisfactory alternative explanation has been offered, the inherent difficulties of which are not even greater.

There appears then to be no generally accepted and scientific explanation as to the why and wherefore of hearing. Wilkinson's criticism of the various theories advanced is rather destructive than constructive, although, of course, such criticism is of value. It is curious that no satisfactory working model of the cochlea has ever been made. A good model of this important part of the labyrinth might greatly facilitate investigations in this direction.

BREAST FEEDING AND THE INFANT MORTALITY RATE.

In countries populated by the white race it is essential that as many healthy children should be born and reared as possible, that is if the white race is to continue its dominance of the world. Unfortunately in all countries the inhabitants of which are white, the birth rate for some years has been steadily declining, and it also appears that the more highly civilized the country the fewer children are born. Also in these countries the educated and those best fitted to rear and bring up the most desirable citizens have the smallest families. However, if the members of the white

racers refuse to have more than a limited number of children, at least, those that are born should be nursed and reared in the manner best calculated to make of them healthy men and women. But even this is not generally done. The infant mortality has certainly been greatly reduced, yet still stands in most countries at far too high a figure. Moreover, it is not only the mortality which is a matter of national or rather international concern, but the invalidity and various disabilities that hamper the adult who was not properly nourished when an infant and whose bringing up throughout childhood and youth was not based on sound hygienic principles. It is, however, in the first few months of life that the die usually is cast, as to whether an infant will develop into a healthy specimen of manhood or womanhood. And this result depends very largely on its diet and the methods of feeding followed. The safest, cheapest, and most satisfactory way of feeding an infant, at any rate up to nine months, is by the breast.

Referring to this subject in the annual report of the Chief Medical Officer of the British Ministry of Health, Dr. Janet M. Campbell gives some very useful advice as to breast feeding. After taking it for granted that the mother's own milk is the only wholly satisfactory food for the infant and that there is no perfect substitute for it, she goes on to point out that breast feeding is by no means always a simple and easy matter. Initial difficulties often arise which discourage the mother, and in the absence of sensible, practical advice may lead her to assume that she is physically unable to nurse her baby. The statement might also have been made that too many mothers are willing to assume that they are physically unable to nurse their babies. Attention is drawn to an unfortunate fact that the medical practitioner has relatively seldom made a special study of breast feeding and that it is frequently left to the nurse or midwife to give advice on that point. If the nurse has not been well trained in this direction she is apt to neglect to give a fair trial to breast feeding and the outcome is that she recommends artificial feeding. As for the routine of breast feeding it is now generally conceded that feeding should be at intervals of not less than three hours from the time of birth onwards and that the interval between the meals should be increased to four hours as soon as possible, no food being given at night between the hours of 10 P. M. and 6 A. M. Thus both mother and child have reasonable rest and from the mother's point of view, breast feeding loses much of its fatigue and inconvenience.

The points which it is desired to emphasize are that it is a matter of supreme importance to the white race to rear the largest number possible of healthy children and that in order to effect this object infants must be nourished in such a way that the foundation of a sound constitution is laid. Further, that this result can be best achieved by

mothers nursing their offspring. Consequently, as Dr. Campbell says, "doctors, midwives, nurses and health visitors should be thoroughly conversant with the practical aspect of the subject and so able to give useful advice which will carry weight with the mother and convince her that it is only right and proper to nurse her own baby, unless there are valid reasons to the contrary, but that the duty will not impose upon her an unduly heavy burden." In the prosecution of efforts to promote child welfare the primary and necessary step is to nurse and care for the child properly during the first year of life. Many mothers fail to do this through ignorance and it comes within the province of medical men especially to advise and instruct regarding the manner and time of feeding and on other matters concerned with the upbringing of the infant. By such means the infant mortality rate will be kept down and adult invalidity and disability will be minimized.

UTILITY OF THE APPENDIX.

DUFOUR in a brief article on this subject in *La Presse Médicale* for October 30, 1920, xxviii, 79, states that in order to appreciate certain problems of the appendix one should study specimens removed during autopsy or post mortem. Three features will be noted: first, the natural mobility, not only as a whole, but of the free extremity; second, the position of the tip of the appendix in reference to the ascending colon or any other portion of the colon within the pelvis, and, third, the presence or absence in the appendicular lumen of any of the intestinal contents. The author differs from the physiologists Morax and Doyon in holding that the appendix is a diverticulum of the cecum, and as such it should give free access to the contents of the intestine, which presumably it is able to expel; provided of course that its canal is permeable. During operation the appendix, when permeable and free from coproliths, contains the normal contents of the cecum for the time. The consistency is semisolid, unless of course a purgative has been given. The normal behavior is somewhat as follows: When the cecum is full the appendix begins to fill until distended and at the same time straightens or unkinks itself, while the free end is mobilized and in all likelihood by contact with some portion of the peritoneum evokes peritoneal irritation, peristalsis, and the desire for stool. The area irritated is most apt to be the peritoneal covering of the colon. If this view is correct, then an adherent appendix has forfeited this power, so that the subject has less incentive for defecation. We know how the subject with this lesion is apt to be constipated. On the other hand, a very long and overmobile appendix could cause too frequent stools, colic, etc. Here is perhaps an indication to operate on an uninfamed appendix.

TESTICULAR OPOTHERAPY.

THE failure of testicular extract in cases where it seems indicated, when contrasted with the brilliant effects of testicular grafts and with the generally favorable effects of so many organ extracts when

given by the mouth, is one of the riddles of therapeutics. Bauer considers the subject briefly in *Le Bulletin Médical* for Oct. 2, 1920, xxxiv, 47. While the interstitial cells of the testicle are believed to contain the active principle of the gland, an extract of the whole organ is usually given. If animals are castrated and glandular extracts injected the effects which should result from the unsexing do not supervene. Extracts have been prepared from human ectopic testicles which consist wholly of interstitial tissue but the results have been disappointing. The good effects claimed for the extract of Poehl are not obtained by those who have tested it. Ever since the first trial of testicular therapy by Brown-Séquard, cures of impotence have been claimed, but these were probably cases of psychical impotence only. Results obtained in children, especially about the time of prepuberty, in cases of anomalies of growth and development, appear to show that the remedy may have some power in the undeveloped male. Souques in fact gives it with other extracts in infantilism. An empirical or chance effect in relieving constipation has been claimed by several who have given the gland to neurasthenics, but apparently only when injected hypodermically. The usual dose has been five grains of the dried extract two or three times daily. The author does not mention either massive doses or the use of the remedy over prolonged intervals of time, but doubtless the treatment would not have been abandoned without a complete trial, including subcutaneous injection.

THE TREATMENT OF TUBERCULOSIS WITH SODIUM MORRHUATE.

SIR Leonard Rogers, who has been instrumental in introducing new methods of treatment for several diseases, has recently been studying the therapeutic value of certain oils, and has somewhat rehabilitated cod liver oil with regard to its action upon the tubercle bacillus. In *Tubercle* for November 1920, Dr. G. R. Iambe of Narsinghpur, India, writes on the treatment of tuberculosis with sodium morrhuate, upon which Sir Leonard Rogers read a paper at the session of the Science Congress in Bombay, Jan. 1, 1919. Most of the cases treated by Iambe were lung cases. Among others he treated three cases of surgical tuberculosis, two of tuberculous glands, and one of tuberculous caries of the ankle and elbow joints. In both the gland cases the glands healed by first intention and the elbow case was markedly improving at the time the report was made. With regard to the pulmonary cases in the early and so-called second stage the improvement was marked and fairly rapid, in fact improvement in all the symptoms of the disease was manifested. According to Iambe, sodium morrhuate, given hypodermically or intravenously, produces marked changes in the bacilli. The envelopes are broken soon after commencement of the injections. Indeed after a course of about six or eight injections, no covering was noticed in a single case. The bacilli themselves undergo degeneration, from their slight curved and unbroken appearance they become beaded and broken. However, they have never wholly disappeared even after as many as 80 injections.

News of the Week.

New York Quarantine Station Goes to Public Health Service.—The United States Public Health Service will take over the New York Quarantine Station formally upon presentation by the State of New York of proof of title to the premises. When the legal transfer is consummated the Federal Government will come into complete possession and administrative control of all quarantine stations in this country. Legislation, first adopted in 1893 and subsequently supplemented, provided for the purchase by the Federal Government of seaport quarantine stations of such States as might be willing to part with them. Most States were glad to be relieved of the expense of carrying on a work that was for national rather than local protection, and one by one have been taken over until only New York was left.

Jones-Miller Narcotics Bill Favored.—At a hearing before the House Ways and Means Subcommittee on January 4, the Jones-Miller bill was endorsed by Surgeon-General Cumming and other government officials. This bill proposes to amend the Harrison act to prohibit all exportation and limit importation of cocaine, morphine, and other narcotic drugs. The importation of the raw drugs is prohibited except in such quantities as may meet the approval of the Surgeon-General of the Public Health Service. Assistant Solicitor G. H. Hackworth of the State Department, says this legislation would be of assistance in meeting the terms of the Hague international anti-opium convention.

Crime and Alcoholism Under the Volstead Act.—Congressman George H. Tinkham of Massachusetts is prepared to show by police court records that 42,000 persons were arrested in the National Capital during 1920, compared with a total of 35,498 arrests during 1917. According to this report most of the fines of 1920 were imposed for drunkenness, bootlegging, disorderly conduct, and traffic violations. The Volstead act is also blamed for a 100 per cent. increase in the number of cases of alcoholism treated in the municipal hospitals of New York City during the past six months in a report submitted by Bird S. Coler, Commissioner of Public Welfare. According to this report there were 807 cases of alcoholism admitted to Bellevue Hospital during the last six months of 1919, and approximately 1,425 during the last six months of 1920. At the Kings County Hospital, where the second largest number of alcoholic cases have been treated, the increase from August 1 to December 8 was 106.6 per cent. Commissioner Coler states that from information furnished by doctors the type of case they are seeing now is different; "that there is no 'fight' in them—that they are just down and out and very unpleasant to handle." This is attributed to the use of "hard" liquor to a greater extent than formerly.

Alleged Deaths from Botulism.—Tinned beef which has been in the galley of the Greek steamship *Iokasto* for four months, has caused the death of its first officer and two cadets. Two other cadets were taken critically ill at the Staten Island Hospital. The *Iokasto* arrived at Quarantine on December 27. During the voyage the ship's food supply was exhausted and a new sup-

ply which was expected at Quarantine did not come, so the crew ransacked the galley and found the canned beef. All who partook of it became ill. Agents of the Department of Health have taken samples of all food aboard the vessel for analysis. The newspapers report these as deaths from botulism, a word which has taken the place, in popular parlance, of ptomaine poisoning.

Campaign for Cardiac Children.—A conference to consider the problem presented by the large number of children of school age who suffer from cardiac troubles was held at the Hotel St. Regis January 6, under the auspices of the committee for the Mineola Home for Cardiac Children. This meeting opened a week's campaign to raise \$100,000 for the support of the home and for nine classes of cardiac children of school age, caring in all for 470 children.

Anthrax from Gloves.—A case of anthrax is being cared for in St. Mary's Hospital, New York, which is believed to have been caused by infection from a pair of undressed kid gloves.

Fund for Cornell Medical College.—At the close of its recent campaign Cornell University's semi-centennial endowment fund amounted to \$8,952,770. Among the various purposes to which this fund will be devoted two interesting items are \$1,500,000 for a new chemistry laboratory and \$500,000 for the medical college in New York City.

Fire Damages Biltmore Hospital.—A fire on January 2 destroyed the central part of the Clarence Barker Memorial Hospital, at Biltmore, N. C. The damage is estimated at between \$40,000 and \$50,000. Plans for rebuilding the burned sections of the building are already under way.

Two Centenarians Die.—Mrs. Sarah Freeman of Woodstock, Ont., a grand niece of Joseph Brant, famous Mohawk Indian chief, died December 30, 1920, at the age of 108 years. She was born in Stockbridge, N. Y., in 1812. George Crow, who died at Denver Hill, near Littleton, W. Va., on January 8, also reached the age of 108 years. He sought to enlist for military service in the Civil War and was rejected by the recruiting officer for his advanced age.

Manidol Songkla, Crown Prince of Siam, is taking a special course in public health at Harvard University and the Massachusetts Institute of Technology.

Mayor Jeremiah Donovan of Norwalk, Conn., has for the third time turned over his year's salary as Mayor to a local hospital to aid in the treatment of those who have not the means to pay.

Dr. Edwin Bradford Cragin, who died October 21, 1918, left an estate of \$1,164,281, mostly in stocks and bonds, as shown by the appraisal recently filed in Surrogate's Court.

In Memory of Dr. Samuel James Meltzer.—The stated meeting of the New York Academy of Medicine of January 6 was held in association with the Society for Experimental Biology and Medicine and the Harvey Society as a tribute of appreciation of the life and services of Dr. Samuel James Meltzer. Memorial addresses were made by Dr. George B. Wallace, Dr. Phoebeus Levene, Dr. William H. Howell, Dr. Graham Lusk and Dr. William H. Welch.

Activities of the New York Academy of Medicine.—The annual report of the president of the New York Academy of Medicine, Dr. George David Stewart, shows that each year the Academy is taking a more active and extended part in the health and related problems of the community, the State and the Nation. Among the many problems that its Public Health Committee has considered during the past year are the following: (1) An exhaustive study of the dispensary situation has been concluded and published. As a result of this study a special committee under the auspices of the Hospital Fund, has been organized to continue the work. (2) At a request of the State Industrial Commission, a committee has undertaken a study of the medical aspects—not political—of the Workmen's Compensation Act in New York State. (3) The committee, in preparing the scientific program of the Milk and Health Exposition held in May, 1920. Among other subjects which the committee considered and upon which it made records, are birth control, the Health Center bill, the way in which Federal grants for stimulating the Anti-Venereal Disease Campaign in the several states were used in New York City. This report sets forth the needs of the Academy, more particularly of the library, and expresses the belief that if the public were aware of the valuable service of this institution to medical education and the study of public health problems the financial aid it deserves and needs would be forthcoming.

Child Welfare Congress in Mexico.—Two hundred physicians from all parts of the republic met in Mexico City, January 2, to attend the first congress on child welfare held in that country. According to the *El Universal*, the mortality among children in Mexico is startling. In Mexico City alone 75 per cent. of the weekly deaths are in children under sixteen years of age.

Health Drive in Spain.—A cablegram from Madrid, under date of January 2, states that in accordance with recent legislation, a national health commission has been nominated which will direct its efforts to the sanitation of the villages and small towns of Spain.

Doctors Needed in Poland.—A recent report made to the American Red Cross by the Ministry of Health states that Poland lost 400 doctors from typhus fever and now has only 4,000 for a population of 28,000,000, or one for every 7,000 persons. The American Red Cross is constantly reinforcing its medical men in Poland for the purpose of helping the local authorities offset their losses in native physicians.

To Aid Sick and Wounded Ex-Service Men.—The New York County organization of the American Legion announces that an organization has been formed for the purpose of visiting sick and wounded ex-service men with the idea of providing expert medical attention for those who are not in hospitals and who are suffering from disabilities resulting from their military service. A committee has been appointed consisting of Dr. Curtin Gillette, Dr. Fenwick Beekman, and Dr. E. M. Colie, Jr., which will consult with and examine applicants and make such disposition of the patients as their condition requires. The following

Consulting Committee has been appointed to aid in the work: Drs. Harlow Brooks, Joseph A. Blake, Brainard H. Whitbeck, Richard T. Atkins, Conrad Berens, Jr., James Bayard Clark, C. Burns Craig and Henry S. Dunning.

Health Department Lectures on Radium Therapy.—A series of lectures under the auspices of the New York City Health Department will be delivered this month stressing the cure of many forms of cancer through the application of radium therapy. It is stated that the object of these lectures is to allay the fear of surgery which deters many persons from consulting a physician while their malignant diseases are in an incipient stage.

Dr. Louis Pearce of the Rockefeller Institute for Medical Research, who has spent six months in the Congo studying sleeping sickness, returned to this country on the *Lapland* on January 3.

New York Hospital Opens Urological Department.—The New York Hospital announces the opening of a urological department in accordance with the terms of the will of the late James Buchanan Brady. For the present both the hospital service and the out-patient clinic of the new department will have quarters at the Hospital.

Harvey Society Lecture.—Dr. Alfred F. Hess of New York University and Bellevue Hospital Medical College will deliver the fifth Harvey Society Lecture at the New York Academy of Medicine on the evening of Jan. 15. His subject will be "Newer Aspects of Some Nutritional Disorders."

Antivaccination War on Staten Island.—A movement against vaccination was started recently on Staten Island, when a man was summoned by the Board of Education for failing to send his daughter to school, the reason being that she had not conformed to the State law requiring vaccination. Ten summonses are expected by others who have taken the same attitude in regard to their children. Antivaccinations have held a number of public meetings recently. To offset the antivaccination propaganda, Health Commissioner Royal S. Copeland called a meeting on Jan. 7 of those who favor vaccination. At this meeting addresses were made by Dr. Copeland, Dr. Leland E. Cofer, Health Officer of the Port, Dr. William H. Park, and Dr. S. Dana Hubbard.

Philadelphia Hospitals Get Whiskey.—Federal Judge Thompson, on Dec. 29, handed down a decision, the first of its kind, which will enable Philadelphia hospitals to purchase confiscated whiskey at the rate of \$3 a gallon. The Judge has designated the hospitals which are to receive the whiskey and the amount to be paid for it. This decision disposes of 690 gallons of whiskey among six institutions and more will be awarded later.

Red Cross Requires Physicians for European Service.—The American Red Cross is desirous of enlisting a number of medical men for service among the children of Eastern Europe. The service is particularly suitable for recent graduates of hospitals who are free to spend a year in the practice of their profession in Europe. The remuneration will be sufficient to represent an adequate salary and living expenses. The men are needed within a few weeks. Further information may be obtained by addressing Dr. Charles M. Berry, American Red Cross, 44 East 23rd Street, New York City.

Banner Year for Babies in Chicago.—According to Health Commissioner Robertson of Chicago, there were 55,316 births recorded in that city during the year 1920, an increase of 8,558 over 1919. The male babies numbered 28,515, while the females numbered only 26,801.

Appropriation to Prevent the Importation of Epidemics.—The Board of Estimate of New York City has granted the request of Dr. Royal S. Copeland, Commissioner of Health, for \$40,000 in special revenue bonds to be used in preventing typhus fever, bubonic plague, and other communicable diseases prevalent in Europe from entering this city.

Obituary Notes.—Dr. GEORGE KNIFE died at his home in New York City on January 5, at the age of sixty-three years. He was graduated from the College of Physicians and Surgeons in 1885. He was a member of the American Medical Association and the New York Academy of Medicine.

Dr. WILLIAM ALLEN BARTLETT of New York City died at his home on January 5, after a long illness. He was born in 1858 and was graduated in medicine from the College of Physicians and Surgeons, Columbia University, in the class of 1881. After graduation he served a term as medical interne at the New York Hospital and then entered upon general practice, soon acquiring a large clientele. He was very fond of athletics of all kinds and was for many years an active member of the New York Athletic Club. He was a member of the New York Hospital Alumni Association, of the Medical Societies of the State and County of New York, and of the American Medical Association.

Dr. JOSEPH ELLIS MESSENGER of New York, a graduate of Bellevue Hospital Medical College in 1879, died after a long illness on January 5, at the age of sixty-eight years. He was director and assistant visiting physician to the Knickerbocker Hospital.

Dr. EUGENE F. FINLEY, a graduate of the University of Louisville, Ky., in 1892, and formerly house physician at Ward's Island, died at his home in Brooklyn, N. Y., on January 6, at the age of fifty-two years.

Dr. MALCOLM SUMNER WOODBURY of Clifton Springs, N. Y., died at the Clifton Springs Sanitarium on January 6, at the age of forty years. He was a graduate of Jefferson Medical College in 1906, a member of the American Medical Association, and the American Society for the Advancement of Science.

Dr. HENRY A. BUMSTEAD of New Haven, Conn., professor of physics at Yale University, died on a train en route from Chicago to Washington, on January 1, at the age of fifty years. He was chairman of the National Research Council. He was graduated from Johns Hopkins University in 1891 and received his doctor's degree from Yale.

Dr. RICHARD KINGSMAN of Washington, D. C., died after a month's illness on January 1, at the age of fifty years. He was a graduate of Howard University School of Medicine in 1886, and a member of the American Institute of Homeopathy. He was director of the Homeopathic Medical and Surgical Club and a member of the medical staff of the Homeopathic Hospital.

Correspondence.

CASES OF CYSTITIS AND PYELITIS OF OBSCURE ORIGIN.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Within the past fortnight I have had three cases of cystitis of obscure origin arising in women and extending to include pyelitis of the right kidney. In all of the cases we had the common symptoms of acute cystitis with pus and blood in the urine; temperature running up to 104° F. but without a marked impression of severe illness in the manner and bearing of the patients. All of them had suffered to a moderate degree from the prevalent "colds." Description of elaborate details is not needed beyond this brief note of salient features when asking the question if others have noted this combination or complication of cystitis and pyelitis occurring with the prevalent colds this year.

All of us who have been long in practice are familiar with the fact that cases sometimes seem to go in groups. I shall regard these three cases of mine as merely one of these curious coincidental groups unless my note calls out response indicating that the observation has certain clinical value.

ROBERT T. MORRIS, M.D.

616 MADISON AVENUE.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, December 17, 1920.

Influenza Decreasing.—According to the figures supplied on December 10 by the Ministry of Health there is at present no influenza epidemic in London. The deaths from influenza recorded for the past four weeks, reckoning back from December 10, were 14, 13, 15, and 13 respectively, while deaths from violence totaled 34. The number of deaths from diphtheria for the same four weeks were 26, 20, 22, and 22, while scarlet fever was responsible for 7 victims in each of the first three weeks and 4 in the last.

Students' Efforts for the London Hospital.—With the object of raising £1,500 students of the London Hospital, Whitechapel Road, are organizing a series of raids. On the morning of December 10 one hundred of them donned operating robes and were conveyed in lorries decorated with banners and appealing inscriptions on a tour of the markets. Smithfield, Billingsgate, Leadenhall, and Aldgate were visited, and at each place a number of checks, treasury notes, coins and promises were obtained. On the evening of the fight between Beckett and Moran at the Albert Hall they took up a position in the corridors and also made a round of night clubs in the West End.

Tuberculosis in Belfast.—The chief medical officer of the city of Belfast has issued recently his annual report. It appears from this report that 2,529 new patients were examined at the institutes and 19,816 old patients attended in the year ending March 31, 1920. Of the new cases 1,820 were found to be tuberculous, 508 non-tuberculous and 352 "suspect." Of the specific forms of tuberculosis, pulmonary cases numbered 698 males and 798 females; glandular, 17 males and 105 females; osseous, 48 males and 48 females; abdominal, 16

males and 11 females, and other forms, 12 males and 7 females. The number of patients under treatment was: institute, 1,575; domiciliary, 3,470; sanatorium, 254. The number treated during the year was 7,251, and included those patients who had left the city, or who did not need further treatment, or who had died. The age-incidence showed that the female rate had two maximums, viz., the quinquennium 10-14 and the quinquennium 20-24; while the male rate showed a maximum in the quinquennium 20-24. The female rate showed an excess over the male rate at the earlier ages, while the male rate showed an excess in the period 35-39 and at later ages. Information is also given with regard to the occupations of the patients. Among the highest figures were the following: discharged soldiers, 338; general servants, 14; clerks, 28; engineers, 35; spinners, 42; stitchers, 72; weavers, 49; winders, 21; doffers, 21; laborers, 208; schoolboys, 194; school-girls, 229. Of the 1,820 patients found to be suffering from tuberculosis during the year 758, or over 41 per cent., admitted personal association with tuberculosis among members of their own families. In many cases it appeared that, as the result of inter-infection, whole families had been wiped out by the disease. Respecting the results of treatment the following figures are given: Domiciliary patients, greatly improved, 385; improved, 1,455; in statu quo, 1,183; worse, 203. The domiciliary patients numbered 3,470. Institute patients; greatly improved, 143; improved, 484; in statu quo, 282; worse, 8. The number of institute patients was 1,575. Sanatorium patients: Greatly improved, 41; improved, 74; in statu quo, 43; worse, 32. Among other things the report shows that under certain conditions tuberculosis is transmitted from individual to individual, given favorable conditions, and it is to be presumed a suitable soil. A certain degree of susceptibility is no doubt essential to the contraction of tuberculosis as well as a favorable environment. At the same time the transmissibility of tuberculosis from person to person has been made the subject of a great deal of exaggeration. There are people who assume that they are as nervous when entering the house of a consumptive as if they were visiting a case of virulent infective disease. Dr. Noel Bardswell in his little work published a short time ago, "Handbook for Tuberculosis Workers" (John Bale, Sons and Danielson) supplies an antidote to the vapors of such as these. The contents of his book are imbued with common sense throughout and full of useful information. The chief medical officer of Health for Belfast lays great stress on the urgent need of preventive measures in the campaign against tuberculosis. He utters the solemn warning that we shall never grapple successfully with the problem of tuberculosis until we cease to turn our attention exclusively to the treatment of the individual. This sounds perfectly true. Educate the masses how to avoid tuberculosis, and segregate those suffering from it, as far as possible, and long steps will have been taken in greatly diminishing the incidence of the disease.

The Prevention of Venereal Disease.—An important addition to the literature on venereal

disease has just been contributed by Sir Archdall Reid, who has brought out a book dealing with the prevention of venereal infection. The author will be remembered by many members of the medical profession in America as the writer of in many respects the best work on alcohol ever published. The present book discusses venereal diseases from various aspects, but of course mainly from the preventive standpoint and with a knowledge drawn from a wide experience. Sir Archdall during the war and after has been stationed at Portsmouth, the British naval port, and there have passed through his hands in the course of the past few years many thousands of men suffering from syphilis or gonorrhea. Therefore, he has been able to form an opinion as to the most effective means of preventing the most dangerous and insidious maladies that can be acquired by the inhabitants of the world. He has formed his opinion, and it is this, that not only can venereal diseases be easily prevented (Metchnikoff drove home this lesson), but that the means of prevention are easily procurable and according to the outcome of his experience not difficult of application. By the way, Metchnikoff taught this lesson also. Reid's prescription for the prevention of venereal disease is prompt and adequate disinfection. It should be said that the book is endorsed by the British Society for the Prevention of Venereal Disease and contains the evidence and arguments on which the Society bases its policy. At Portsmouth the system has been a conspicuous success and also, according to Reid, on every occasion when disinfection has been done properly and sufficiently promptly. The book puts the case for the Society lucidly and cogently and should be read widely even if it does nothing more than give rise to discussion. The whole subject of direct prophylaxis needs ventilation. So long as it is not understood or misunderstood just so long will headway be impeded with regard to the prevention of venereal diseases. The scheme suggested in the book may not be practically applicable to a civilian population but, at least, the medical profession and the public should be afforded every opportunity of judging. This book gives much information regarding many moot points of the venereal problem.

The Tuberculosis Bill.—Dr. Addison, Minister of Health, in answer to a question asked in the House of Commons a short time ago, said that considerable additions have been and are being made to the available accommodation for the sanatorium treatment of tuberculous ex-service men and to the facilities available for the concurrent treatment and training of these men. Provision is made in the Tuberculosis Bill for the establishment of village settlements and employment colonies for the benefit of tuberculous patients and their families. Dr. Addison, however, went on to say that owing to the pressure of Parliamentary business it would not be possible to pass the bill this session.

Medical Service for Scotland.—An Interim Report has been presented by the Scottish Consultative Council on Medical and Allied Services recommending a scheme of medical service for Scotland. The report has been adopted by the

Council. The following is a summary of the recommendations. (1) Unification of all local health authorities; (2) a complete medical service to be within the reach of every member of the community, organized by the State, but not of necessity provided at public expense or carried out by State officials or practitioners; (3) organization to be based on the family as the normal unit and the family doctor as the normal medical attendant; all health agencies to be mediated to the individual by the family doctor; (4) the expansion of the present insurance system to provide for the whole population of "national insurance" grade, including all dependents, those entitled to medical service under the Poor Law, and for the treatment of discharged soldiers; (5) special services to be available to others above "insurance" grade for which that section of the community is unable to make adequate provision; (6) the provision of small "recovery homes" or "hospices" for cases of ordinary illness where the patient cannot be properly treated at home and where no "cottage hospital" or nursing home is available; (7) the provision of "invalid homes" for chronic invalids; Poor Law hospitals might be used for that purpose; (8) the family doctor to be provided with all necessary supplementary advice and assistance; all serious surgical cases to be sent to hospital for operation; for acute medical and other cases "district consultants," selected by local members of the profession to be appointed; ambulant cases to receive advice at hospitals or consultation clinics; cooperation among general practitioners for consultation and treatment to be encouraged; (9) facilities to be provided to all practitioners and to all classes for reference to clinical laboratories, and to experts in special branches of medical science; (10) the recommendations regarding hospitals are reserved pending the report of a joint committee considering the question; (11) convalescent homes should be increased in number, and include "preventive" or "rest" homes; (12) the Queen Victoria Jubilee Nurses' organization to be utilized as a suitable basis for a national system of skilled district nursing; (13) the provision of fully trained health visitors in populous areas; (14) the provision of an adequate maternity service as soon as a sufficient number of trained midwives is available; a necessary adjunct would be the provision of sufficient beds in each district for difficult cases or where the home conditions are unsuitable; (15) adequate facilities to be provided for dentistry; a consulting dental surgeon to be attached to each laboratory clinic; (16) the pharmaceutical arrangements of the scheme, it is recommended, should follow the provisions of Section 15 of the National Insurance Act.

OUR LETTER FROM GENEVA.

(From Our Own Correspondent.)

GENEVA, Dec. 1, 1920.

International Congress of Anthropology.—A few weeks ago the School of Anthropology of Paris convened an international reunion of scientists at Paris and this congress, at which some fifteen countries were represented, was an unquestionable

success. Quite different from most congresses at which the results of researches are reported, the Paris congress had as its essential aim to propound questions and to consider methods of research work. As the anthropological sciences have developed very considerably during the past few decades special commissions were at once appointed for anatomical and zoological anthropology, human paleontology, ethnology, and ethnogeny, criminal and prehistoric anthropology, etc. Each commission thus organized worked without remission and on the concluding day of the meeting a certain number of recommendations—all unanimously adopted—were made to the plenary session, much material for discussion was suggested, and various resolutions were offered.

It is impossible here to give in detail the resolutions accepted, but some of the most important may be briefly mentioned. The question of ethnic cross-breeding was generally accepted as being of capital importance on account of our present ignorance in respect to its real results. For example, is a given instance of cross-breeding necessarily advantageous or disadvantageous? Objective facts are still wanting to produce scientific basis for judgment on the question, which is, in reality, very serious, especially that of consanguineous marriage. The study of the physical capacity of children, examined from the viewpoint of professional value, was the object of a discussion during which an attempt was made to establish a scientific basis for the anatomo-physiology of the child during school life.

Questions of eugenics naturally were discussed and among the resolutions voted there was one whose aim is the study of the somatic and psychological characters attesting the biopsychic inferiority of certain individuals. After a discussion of the past due respectively to heredity and environment in the development of this inferiority, the means for preventing or attenuating the occurrence of characters detrimental to the health and hygiene of the human race were considered. As to the word "race," we are all familiar with the various interpretations given it. The ethnological commission remarked that until now the study of human "races" has consisted only in a description and comparison of various human groups, in certain geographical regions, momentarily bearing certain names of people and speaking for the time being a given language. Therefore, although recognizing the interest—and the necessity—of researches made in this direction up to the present and their continuation, the commission was of the opinion that these were merely the first stages of much greater work.

In point of fact, although these analyses have already led to a more or less synthetic image of such or such a group, geographically, linguistically, and politically defined, it is, nevertheless necessary to go further and attempt to discover in each human group its hereditary lineages, by noting the constant characteristics of a given population, in other words its genealogical characters. In this way we shall at length be able to distinguish by initial ethnic types, which are the basis of our present lineages. It was even proposed that these present ethnical types, which thus become extri-

cated from the chaotic condition in which they have been, should be known not merely in their morphological but likewise in their physiological and psychological characters. These propositions, which I have here outlined perhaps represent one of the most considerable labors of anthropologists to come.

In the domain of anthropological statistics a greater coordination was advised between statisticians and technicians in order to reach more useful results. Prof. Pittard of Geneva is of the opinion that great progress can be made in this direction to the undeniable advantage of medical and sociological science, and he also points out the great merit of the resolution voted that, in the domain of prehistoric archeology, all future excavations should be carried out with a single aim in view and with exclusively scientific methods.

More extensive and active international relationship was also unanimously voted and systems of exchange of documents and lectures, the creation of a scientific international annual, the publication of an anthropological dictionary bringing up to date all discoveries and scientific results at present acquired by observers of all countries, the establishment of a central bibliographical organ, etc., were advised. Finally, a recommendation put forward by a large number of members and accepted unanimously by the assembly, demanded a much greater development in the teaching of anthropology in all its aspects in all institutions of advanced learning.

9. Spina Bifida. Torr Wagner Harmer.

7. Clinic on the Diagnosis and Treatment of Neurosyphilis.—H. C. Solomon, concluding his discussion of this subject, points out that: 1. The central nervous system is involved by syphilis very frequently in the primary and secondary stages; that this involvement is ordinarily benign and disappears symptomatically with or without treatment. 2. In a small number of cases, acute meningitis, meningocephalitis, vasculitis, and gummas occur in the secondary period of the disease. 3. About 10 per cent. of all cases of syphilis develop late neurosyphilis, tabes, paresis, meningitis, meningocephalitis, gummas, vasculitis. 4. Neurosyphilis is always serious, affecting the mind, utility, and life of the patient. 5. Diagnosis is often possible only by the aid of the spinal examination. 6. Therapeutic results are better, the earlier the diagnosis of syphilis is made, and the sooner treatment is instituted. 7. The spinal fluid is often positive long before definite symptoms are present; hence the need of frequent lumbar punctures. 8. More intensive treatment is usually required to treat neurosyphilis than in the treatment of non-nervous-system syphilis. 9. Cases of meningitis, acute meningocephalitis, and mild vascular syphilis usually react favorably to intensive intravenous injection. 10. For these conditions intraspinal injections will at times accomplish more than intravenous therapy.

11. Tabes is more difficult to improve than the above mentioned forms. Many cases, especially the early ones, show improvement under intravenous therapy ad-will at times accomplish more than intravenous therapy. will frequently do much better. It is often the method par excellence. 12. Many cases diagnosed as paresis make fair recoveries under intravenous therapy. 13. Intraspinal injections and drainage of the cerebrospinal fluid may aid in the intravenous treatment of general paresis. 14. Intraventricular injections may at times give more favorable results than any other in the treatment of paresis.

2. Dangers to Life Associated with Gallstone Disease and Their Prevention.—Benjamin T. Tilton directs attention to the four chief dangers that may threaten the life of the carrier of gallstones. 1. Acute suppurative or gangrenous cholecystitis; 2. cholangitis; 3. malignant disease of the gallbladder; 4. operation in delayed cases. In the severer types of acute suppurative or gangrenous cholecystitis operation should not be delayed in the severer types of cases. Simple drainage of the gallbladder is the operation of choice in the severe cases. Cholangitis usually implies that one or more gallstones have entered the common duct and caused stoppage of the flow of bile, with resulting infection. The choice of the time for operation in these cases is a matter of judgment on the part of the surgeon. Operation is more hazardous at the height of the attack and in the presence of jaundice, but if the symptoms persist more than forty-eight hours and the patient's general condition is growing worse from the absorption of septic bile, operation offers the best chances and should not be further delayed. Here also the simpler and shorter operation for drainage of the gallbladder will meet the vital indications, and will save the patient's life in cases where the patient would succumb to the more complicated and prolonged operation of cholecystectomy and removal of the stones in the common duct. Malignancy starting in the gallbladder, unfortunately, in most cases, is too far advanced when diagnosed to admit of complete surgical removal. Metastases in the liver are not amenable to surgery, and it is only when the disease is localized in the wall of the gallbladder that surgery is successful. Operation in delayed cases of cholelithiasis is often hazardous. Early operation in cholelithiasis is strongly indicated; only in this way can the present high mortality of this serious disease be lowered.

3. Pathogenesis and Physiopathology of Gallbladder and Biliary Tract Lesions.—Vincent Anthony Lapenta reduces his views on this subject to the following: 1. Diseases of the gallbladder and biliary ducts are principally produced through hematogenous infections. Importance must be accorded in the history to the occurrence of typhoid, tonsillitis, and other focal infections in the past history of the patient. Previous disease of the vermiform appendix must also be taken into account, as well as concomitant incidence of chronic appendicitis. 2. Oddi's researches show that the gallbladder is not a functionless organ, and that the addition of mucus in the bile by the gallbladder is of some importance. In uncomplicated cases of cholelithiasis with the absence of structural lesions of the gallbladder, without acute or quiescent infection, cholecystectomy is still sufficient. 3. Caution must, of course, be exercised to avoid leav-

ing in a diseased organ. On the slightest evidence of chronic infection, cholecystectomy must be performed. 4. The rôle of hypercholesterinemia in the etiology of gallstones is regarded as a predisposing one. The chief pathogenic rôle is to be ascribed to infection. 5. The rôle of gallbladder infections as chronic foci, capable of setting up systemic metastatic lesions elsewhere in the body, leads one to emphasize the necessity of timely diagnosis and the importance of cholecystectomy as a curative operation.

4. **Treatment of Salivary Fistula by Massage and Hot Air.**—Pierre Koudindj holds that before deciding upon surgical intervention in the treatment of salivary fistula it is essential that one first attempt a physiotherapeutic treatment, composed of appropriate massotherapy maneuvers, as, for example, superficial and deep rubbings, light pressure, digital vibrations, and a current of hot air applied by way of the mouth to the two surfaces of the jaw, first the cutaneous surface, later the mucous surface. It is necessary to combine the two physical agents so that the hyperemic action of the one is complemented immediately by the mechanical action of the other; so that the vital activities of the patient's tissues are stimulated and the cicatrization of the fistula is completed.

2. **Involvement of Nervous System During Primary Stage of Syphilis.**—Wile and Hasley, continuing studies reported in 1915, discussing the findings in 221 cases of syphilis, observed since that time, in which only the primary sore was present. The early period at which these cases were studied is indicated by the fact that of this number 106 were still negative in the blood at the time of the examination. The results which they record refer only to subjective and to biological findings in the spinal fluid. Deviations from the normal in the spinal fluid of these 221 cases of syphilis, in which only the chancre was present, was found in 49 cases, or 22 per cent. of the cases examined. Increase in globulin and albumin virtually parallel was the most constant of the abnormal findings, occurring in twenty-five of the forty-nine cases. Pleocytosis was the next most frequent finding, occurring in twelve cases. The positive Wassermann test in the fluid occurred less frequently than the other two findings, being present in but eight cases. Within certain limitations any single one of the above-mentioned deviations from the normal occurring alone must be regarded as evidence of early central nervous system involvement.

3. **Precautions Necessary in the Selection of a Donor for Blood Transfusion.**—Lester J. Unger summarizes his views on this subject as follows: (1) All individuals may be grouped broadly into four main groups. These groups are established by the presence of two "chief" agglutinins in the serums and receptors for these agglutinins in the cells. Besides "chief" agglu-

tinins, "minor" agglutinins have been demonstrated. (2) Ninety-seven per cent. of adults have agglutinins in their serums. They are, however, present in 13 per cent. of new-born infants. Only 25 per cent. of new-born infants have cells that can be agglutinated, as compared to 50 per cent. among adults. The full quota of agglutinins and receptors is acquired between the third and fourth years of life. (3) Incompatibility between the blood of a mother and her new-born infant occasionally occurs. It is unsafe, therefore, to omit testing the blood preliminary to transfusion, even though the mother should act as donor. (4) It is not advisable indiscriminately to use the so-called "universal donor," as severe reactions have been observed following the use of donors of group IV for patients of other groups. (5) The rouleaux-formation substance, even though acting on the donor's cells, is apparently harmless, and no untoward results have been seen following such transfusions. (6) It is unsafe to perform a transfusion, relying simply on the fact that donor and patient are of the same group. Preliminary to transfusion, the blood of every patient should be grouped and then tested directly against that of the prospective donor.

6. **High Grade Heart Block.**—S. Calvin Smith discusses the influence of posture, respiration and exercise in a case of high-grade heart block in a young man of twenty, illustrating the text with electrocardiograms made under different circumstances. This condition in an active youth of twenty years, with negative previous history, has evidently existed since childhood, despite the fact that heart block is usually encountered in persons past the meridian of life with definite histories of previous infections, and despite the fact that the average life expectancy in high-grade heart block is three years. The case was studied under various circumstances, including the changes induced by posture, respiration, exercise, vagal pressure, and drug administration; the graphic records indicated that on forced expiration the heart block disappeared and that a normal sequence of cardiac events ensued. Fluoroscopic study confirmed these findings. Roentgenograms indicated that the position of the heart was altered when the cardiac mechanism became experimentally natural, thus suggesting that the lessening of traction or the relief of pressure on heart tissue may play a part in the experimental reestablishment of natural cardiac rhythm.

4. **The Clinical Aspects of Enteric Group Infection as Modified by Protective Inoculation.**—J. R. Harper bases his consideration of this subject on experience gained while working in one of the largest special hospitals in the north of France, where special facilities were given for the reception, treatment, and bacteriological investigation of this variety of case. From January, 1915, to December, 1918, 5586 cases were admitted in which enteric was suspected, 3203, or 55.5 per cent. of which were subsequently diagnosed enteric. The positive cases were made up as follows: 1164 typhoid, 36.2 per cent.; 428 paratyphoid A, 13.5 per cent.; 1128 paratyphoid B, 36.8 per cent.; 431 enteric group, 13.5 per cent. In the inoculated men, 150 of whom were carefully studied, the following were the most common signs and symptoms in their order of frequency: Headache, 83 per cent.; pyrexia (ten days or over), 77 per cent.; furred and tremulous tongue, 49 per cent.; rose-red spots, 45 per cent.; slow pulse, 39 per cent.; tenderness in the left hypochondrium, 38 per cent.; palpable spleen, 34 per cent.; abdominal distention, 17

per cent.; epistaxis, 3 per cent.; thrombosis, 2 per cent. Complications were by no means so common or so severe as might be anticipated, even among the un inoculated. The chief complications noted were bronchitis, pleurisy, bronchopneumonia, and lobar pneumonia, cerebrospinal symptoms, appendicitis, perforation of the bowel, hemorrhage, thrombosis, miscellaneous abscesses, epididymitis. An accurate diagnosis of enteric group infection can follow only as the result of the intimate working of the clinician and the bacteriologist. In probably 70 per cent. of cases the clinician experienced in this group infection will be able to diagnose it as such, but it is impossible for him to decide from the clinical picture which member of the group is the causal organism. A positive diagnosis can be made only by the isolation of the specific organism, or by the fact that the patient has acquired an immunity to one of the organisms. The various methods of diagnosis mentioned are: Cultivation of the bacillus, agglutination, atropine test, cardio-ocular reflex (Ascher). The case mortality of paratyphoid was only 1.28 per cent., that of paratyphoid A being even lower. The mortality among all the cases of enteric group infections occurring with the B. E. F. in France was 3.58 per cent. Paratyphoid A is undoubtedly the mildest of the three infections, and typhoid the most severe.

6. Achylia Gastrica.—T. Izod Bennett considers that the vast majority of cases, judging from an examination of the literature, have been put into this category without sufficient justification. A person without gastric hydrochloric acid is deprived of (1) a useful but merely accessory agent for protein digestion; (2) a useful but accessory agent for controlling the action of the gastric sphincters; (3) an important but not essential means of diminishing bacterial growth in the intestines. Appreciation of these facts explains the mildness and frequent absence of symptoms in such cases; it also arouses speculation as to the possible vital importance of achylia in the pathogeny of such diseases as pernicious anemia and cirrhosis of the liver, which are probably infective in origin. One is next confronted with the problem of treatment, and it is immediately evident that if an attempt is to be made to replace the normal acid large doses must be given. If the volume of a meal be put as low as one pint a dose equal to 90 minims of the B. P. dilute hydrochloric acid must be added in order to raise the acidity of the gastric contents to 0.1 per cent. HCl. But a pint is a very small volume for a meal, and if there be much protein in addition a correspondingly larger quantity of HCl must be added. The writer quotes Crohn as having come to the conclusion (1) that single doses of HCl given before meals are useless; (2) that small doses are always useless; and (3) that only by giving large doses throughout meals can any appreciable percentage of HCl be assured in the gastric secretion. Bastedo is quoted as expressing a similar opinion and as speaking hopefully of the effects of acidol, a proprietary preparation of betaine hydrochloride, which may be taken as a solid, and which liberates free HCl on solution. Pepsin should be given at the same time, and from clinical experience one is forced to the hopeful conclusion that even small percentages of HCl may lead to very material improvement in symptoms.

1. The Diagnosis of Acute Abdominal Crises.—Arthur H. Burgess, in two post-graduate lectures here given in abstract, discusses the diagnosis of acute abdominal crises in a general sense, and considers, first of all, individually, the various symptoms and signs met with in such crises, attributing to each its relative value

as a factor in diagnosis, and as an indication for treatment; and secondly, these same symptoms arranged in groups, such as are observed clinically in the different types of abdominal crises. The general symptoms include: (1) Various degrees of shock or collapse; (2) alterations in the frequency and character of the pulse; (3) changes in the temperature; (4) alterations in the type of respiration—"thoracic" type; (5) other symptoms, such as a dry and furred condition of the tongue, hicough, stranguary, and tenesmus. Speaking generally, one may say that, although these general symptoms are useful in directing attention to the possibility of a crisis having occurred, yet they give no clue to its nature, nor are they alone of much value as indications for treatment. It is, then, mainly upon the local symptoms and signs—those referable to the abdomen itself—that one must rely in deciding questions of diagnosis and treatment in any acute abdominal crisis. These include: (1) Abdominal pain; (2) cutaneous hyperalgesias ("viscero-sensory" reflex); (3) tenderness, local and general; (4) nausea, vomiting; (5) muscular rigidity ("viscero-motor" reflex); (6) abdominal distention; (7) presence of free gas in the peritoneal cavity; (8) presence of free fluid in the peritoneal cavity; (9) local abdominal or pelvic swelling; (10) certain changes ascertainable upon rectal examination. Before deciding in any given case presenting symptoms suggestive of an acute abdominal crisis that the cause is referable even to the abdomen at all, two fallacies in particular should be borne in mind; (a) The "crisis" met with in *tabes dorsalis*—"gastric," "intestinal," and "renal." It should be a cardinal rule to test the knee-jerk in every abdominal case. On the other hand, it must be realized that *tabes* does not preclude the coexistence of a true abdominal crisis, and, further, that visceral analgesia which occurs in some tabetics and prevents the manifestation of pain, cutaneous hyperalgesia, tenderness, and rigidity, may render the recognition of such crisis a very difficult matter indeed. (b) The possibility of confusion between acute abdominal crises and acute intrathoracic diseases, especially acute basal pneumonia, acute diaphragmatic pleurisy, and acute pericarditis. This difficulty is sometimes a very real one, and surgeons of experience have not infrequently opened the abdomen only to find the peritoneal cavity normal and the lesion an intrathoracic one. Whenever acute *lobar pneumonia* follows within twenty-four or forty-eight hours of an "early appendectomy," one cannot help but suspect that the pneumonia was the real cause of the abdominal symptoms and that the operation was unnecessary; when pneumonia is due to an operation, it is of the *lobular* or bronchopneumonic type. Confusion is particularly liable to arise in young children, since they cannot assist with a description of their symptoms, and since in them the physical signs of pneumonia are sometimes delayed for twenty-four or even forty-eight hours. Having excluded these possible fallacies, and having decided that one is dealing with a true abdominal crisis, the possible cause of the condition is next to be considered. For his own guidance the writer is accustomed mentally to classify the causes into five groups: (1) The colics; (2) the perforations; (3) the hemorrhages; (4) the inflammations; (5) the obstructions. In conclusion, the writer emphasizes the importance of early diagnosis. The time that has elapsed between the onset of the attack and the opening of the abdomen is the real deciding factor in the ultimate issue of the case—far more so than the skill of the individual surgeon. He believes he speaks for all surgeons when he says that he infinitely prefers to meet in consultation the practitioner whose diagnosis, made in the early hours of the attack, is limited to "something gone seriously wrong in the belly" than one who, *forty-eight hours later*, can give a cut-and-dried and possibly perfectly correct description of what an operation will reveal.

3. The Effect of Pregnancy upon the Size and Weight of Some of the Organs of the Body.—P. T. Herring bases the following conclusions on observations made on the female albino rat: In the healthy albino rat the occurrence of pregnancy has little effect upon the length and weight of the body, excluding the increase of weight due to the uterus and its contents. The heart, kidneys, and spleen are little affected; there is certainly no enlargement of the heart in pregnancy. The liver is

greatly enlarged. The thymus undergoes rapid involution, and is much diminished in size. The suprarenals are slightly hypertrophied. The thyroids are diminished in size in pregnancy, and there is a notable diminution in the weight of the pituitary body, attended by histological changes in its glandular lobe.

1. Medical Aspects of Carcinoma of the Breast.—Robert Hutchison holds that recurrence in the internal organs after removal of the breast for cancer, or the deposition of secondary metastases in various parts of the body, may give rise to clinical symptoms and signs, which are often difficult of interpretation and which lead to errors of diagnosis. The lung and pleura are more often involved than any other organ, when recurrence takes place after removal of a breast for cancer. The symptoms are those of primary carcinoma of lung or pleura. Recurrence in the mediastinal glands without direct involvement of a lung sometimes occurs. The symptoms are those of mediastinal tumor. Recurrence may be mainly in the abdomen, and if the peritoneum is extensively involved, a puzzling picture may be presented. The bones may be the seat of recurrence or metastasis, forming a characteristic group. The writer recalls two cases in which great thirst and polyuria were the prominent symptoms in recurrence after mammary cancer. Not uncommonly cases are met with which are characterized chiefly by the occurrence of neuralgic pains in various parts of the body. Recurrence or metastasis may take the form of an intracranial growth with all the usual symptoms of a cerebral tumor. Cases are given in brief to illustrate the different categories mentioned.

Le Progrès Médical.

October 23, 1920, xlviii, 43.

Origin of Pellagra.—Bory gives a short résumé of recent labors in this field, with special reference to the part played presumably by vitaminic deficit. He quotes from a recent article by Goldberger and Wheeler in which a certain restricted diet appeared to be responsible for the appearance of the disease in prisoners. This diet was restricted to cereals, presumably decorticated. Two months were required for the development of the disease picture, which was classical. Other inmates of the prison, staff members, etc., who were on a balanced diet, presented none of the manifestations. In an insane asylum with cases of pellagra the staff did not contract the disease and an increase in the ration of meat and milk—which had been extremely scanty—appeared to control the disease in the inmates. There were further tests made in orphan asylums and in small villages where pellagra had appeared, with the same results. There is no doubt, then, that pellagra is a deficiency disease, but we do not know whether a vitamin or an amino acid or a mineral ingredient is at fault. The general result is, moreover, offset by the appearance of pellagra in well to do and well fed individuals. But on close inspection some of these were found to have a repugnance to certain dietetic articles—eggs, milk, meat—while others restricted their diet because they regarded certain articles as of difficult digestion. These people showed improvement under the theoretic diet. The author is not satisfied with the dietetic explanation alone, and believes that subjects on an exclusive cereal diet fall victims to some obscure infection. The old spoiled maize theory still holds good in support of this view (recently he could add that experiences in Roumania were due frankly to this cause). He cites an endemic case in France of obscure etiology in which Italian laborers may have brought the germ

from some pellagrous locality. He invokes a mosquito theory of transmission. The diet was favorable for infection, having been largely cereal and not properly balanced.

Le Progrès Médical.

October 30, 1920, xlviii, 44.

New Form of Epidemic Encephalitis.—Hanns describes a case which recently occurred at the Medical Clinic at Strasbourg. The patient, a girl of 19, was attacked suddenly in the midst of health with sore throat, which suggested diphtheria. This was readily excluded by examination of smears. A rash was the next manifestation, and then agitation which culminated in delirium, in the course of which she attempted to jump from a window. She was taken to the hospital, where she was found to be prostrated and cyanotic, these and other symptoms having motivated a bronchopneumonia. There was an intense conjunctivitis, while the exanthem already mentioned was most marked on the extremities, where it was confluent, the digits being swollen but free from all sensations. The closure of the eyes was apparently from photophobia alone. Close observation, however, showed that ptosis was associated with the blepharospasm. The throat was angry and covered with a white membrane. There was no somnolence, but marked rigidity of the nucha with a notable Kernig. Lumbar puncture negative. Despite double bronchopneumonia the temperature was but slightly elevated, save at evening, when it did not exceed 39° C. The delirium was shortlived, as was also the rash; and at the end of eight days all of the symptoms had cleared up. The appetite had been good throughout. The question is now raised as to the diagnosis. This had to be based on the cerebral symptoms, the presence of ptosis (so seldom absent in these patients), the recent prevalence of the epidemic disease, and the resemblance of the case to an atypical one of the latter. But the angina, the peculiar rash and the intense conjunctivitis have never heretofore been recorded as among the symptoms belonging to this disease.

Schweizerische medizinische Wochenschrift.

November 11, 1920, I, 46.

The Wildbolz Individual Reactions.—Imhof, assistant to Wildbolz, gives a detailed account of the urine and serum reactions first discovered by the latter in connection with the diagnosis of tuberculosis. As should be well known by this time to medical men the reaction is a sort of von Pirquet in which the inoculated substance is either the urine or serum of the patient himself—a species of autoserodiagnosis. The active substance involved is a tuberculous antigen, as in the case of all specific reactions in tuberculosis; so that the only peculiarity in the Wildbolz is the source of the antigen. The same difference is seen, of course, in therapeutic sera. The chief points of interest are the percentage of negative cases and the ability of the reaction to develop in the non-tuberculous. The presence of two sources of antigen makes double inoculations possible. Thus far patients positive to the urine inoculation have also been positive to the serum tests with few exceptions in which with positive urine there was a negative serum test, or the converse. In all of these a technical error of some sort was accused. Cases are given in which with a clinical diagnosis of tuberculosis the reactions were negative, and others of positive results in non-tuberculous cases. The few observations are merely paradoxical, and in the absence of autopsy finds the real nature of the disease remains naturally in abeyance. Perusal of such histories shows no record of the control use of the von Pirquet or any other specific reaction. Positive results obtained in cases admitted for chronic appendicitis and other chronic suppurations were clearly due to associated tuberculous foci in the body. In extensive organic disease of the kidney, whether tuberculous or not, the elimination of the antigen may be interfered with and consequently in such a case only the serum can be used in a test.

Society Reports.

SOUTHERN MEDICAL ASSOCIATION.

Fourteenth Annual Meeting, Held at Louisville, Kentucky, November 15, 16, 17, and 18, 1920.

THE PRESIDENT, DR. E. H. CARY, OF DALLAS, TEXAS, IN THE CHAIR.

(Concluded from page 77.)

Breast-Fed Babies Who Cry at Night.—DR. EUGENE ROSAMOND of Memphis read a paper with the following conclusions: (1) Habitual crying in breast-fed babies at a particular time each day—usually late afternoon and at night—is a pathognomonic symptom of hunger. (2) The preternaturally smart, wideawake baby is hungry. (3) Three-months colic is primarily hunger. Starvation, indigestion, and milk imbalance due to the mother's worry, may cause true colic to supervene, but these right themselves if the baby's cries are hushed. (4) Supplemental and complementary feeding is the remedy. (5) Complementary feeding should be given only with a cup and spoon.

On the Administration of Digitalis to Children with Diphtheria.—DR. H. MCCOLLOCH of St. Louis presented a communication of which the following were the conclusions: (1) Diphtheria toxin produces either experimentally or clinically anatomical and functional changes in the structures of the heart by direct action. Clinical manifestations of cardiac failure are due to these alterations of function and not to changes in the vagus center or nerve. (2) The effect of diphtheria toxin on the heart is similar in many ways to the effect on the heart of digitalis, either directly or through the vagus nerve. (3) The administration of digitalis to patients with diphtheria is contraindicated because there would result a summation of effects in the same heart. (4) With our limited means of estimating the optimal therapeutic amount of digitalis, or in controlling its effect on the various structures of the heart, this summation constitutes a real danger to the life of the patient. (5) Measures for providing rest for the heart other than the administration of digitalis should be adopted.

The Dietetic and Medical Treatment of Gastric and Duodenal Ulcers.—DR. SEALE HARRIS of Birmingham, Ala., said that the early diagnosis of ulcer of the stomach or duodenum was of as much importance as the early diagnosis of tuberculosis, because if treated properly before the chronic inflammatory changes had continued too long the ulcer healed with but slight cicatrix, and the cure was apt to be permanent; whereas in the old neglected cases it was much more difficult for the ulcer to heal and recurrences were more frequent. The treatment of gastric and duodenal ulcer should be thorough and systematic with attention to details, which accounted for success in any undertaking. Absolute obedience of the patient was important, and happily ulcer patients could be depended upon to give the most intelligent cooperation with the physician. Rest in bed for a period of three or four weeks, preferably in a hospital or infirmary, should be insisted upon and the patient should be under direct observation from six to eight weeks and should report symptoms to his physician for six months or a year, whether the patient was treated medically or surgically. Every case of gastric or duodenal ulcer should be thoroughly examined by a competent nose and throat man for evidences of focal infections in the nasal passages or sinuses, and for infected tonsils. The diet was of greatest importance and should be carried out thoroughly and systematically. In treating gastric and duodenal ulcers either medically or surgically it should be remembered that it was a secondary condition with which we were dealing, and one which was likely to return unless the underlying causes were sought for and removed.

Some Remarks on Gastric Lavage and the Proper Medicaments Therein.—DR. GEORGE M. NILES of Atlanta said that in chronic gastritis with excessive mucus, a lavage two or three times weekly was generally of aid. The lavage habit into which some patients lapsed, was an unfortunate one. These individuals, having learned to use the tube themselves, and finding

that the emptying of an over-distended stomach would bring relief from epigastric distress, made it a practice to hasten for the tube, and wash out the stomach with the first qualm. Some of these misguided sufferers washed out their stomachs from two to four times daily, bringing their bodies to the verge of caloric bankruptcy by their unwise zeal. It was allowable, under certain circumstances, to teach the patients how to administer to themselves a gastric lavage, when they lived in isolated localities, or when it was impracticable to see the physician at the proper time. Such instruction should be leavened with caution, and the patient informed of the dangers that lay in wait for those who fled to the stomach tube, not wisely but too often. In conclusion, he might say that gastric lavage, employed for a definite purpose, under restriction, and in a deft manner might and should fill a worthy place in gastric therapeutics.

Some Observations on the Fractional Analysis of the Gastric Contents.—DRS. JULIUS FRIEDENWALD and ZACHARIAH R. MORGAN of Baltimore, from a study of 210 cases in which fractional analyses were made, believed that the following conclusions might safely be drawn: (1) By means of fractional analyses we can study the entire cycle of digestion both as to the secretory and motor activity of the stomach. (2) By complete aspirations at any period of digestion we can obtain definite information regarding the amount of secretion. (3) In duodenal ulcer the acidity is usually higher than in any other condition. There is a rapid prolonged rise followed frequently by a fall and a secondary rise, though there may be a continuous prolonged rise from the onset. The highest acidity appears frequently after an hour. Blood is at times found in the contents which lends additional evidence as to the presence of an ulcer. Rapid evacuation is rather characteristic of uncomplicated forms of duodenal ulcer. (4) In gastric ulcer there is no typical curve of acidity though a fall followed by a secondary rise is frequent. Hyperacidity is usually present though there may be a low acidity or a normal acidity, the highest acidity appearing after an hour in most cases. Blood is obtained at times in the gastric contents, which presents further evidence in favor of ulcer. There is usually delayed motility in gastric ulcer. (5) By means of fractional analyses the acidity in any period of the cycle of digestion in ulcer may be noted. The highest acidity frequently occurs after an hour and occasionally before, so that its appearance would be entirely overlooked should we rely entirely upon the hour extraction. (6) The effect of an ulcer curve upon the hyperacid secretion can be followed by means of fractional analysis. In but half the cases, however, is a decided reduction in acidity obtained even though clinical improvement may be noted indicating that the symptoms ordinarily attributed to the excess of acid are not necessarily due to this factor. (7) In pyloric stenosis there is usually a high acidity during the whole period of digestion with delayed motility. Food shreds are observed in the fasting state. (8) In most instances of gastric carcinoma one finds a typical achylia frequently with delayed motility and a rather high total acidity and with lactic acid and blood. The Wolff-Jung-hans test is positive, considerable amounts of albumin being present within three-quarters of an hour, being markedly increased within an hour to an hour and a half. (9) Cases of chronic gastritis present the same characteristics as are usually observed in simple achylia. The total acidity is usually higher, however, and in addition mucus is obtained which is not frequently observed in simple achylia. The motility of the stomach is often delayed. (10) In gastric syphilis the curves of acidity are similar to those observed in cancer. The total acidity is high and there is a complete achylia, the stomach emptying itself rapidly. (11) Fractional analysis of the gastric secretion according to the Rehfuess method is extremely important in all cases of achylia gastrica, inasmuch as by means of this method one can easily differentiate the true achylia from the spurious forms. This differentiation is extremely important, inasmuch as many of the false achylia present a very high HCL acid index; sometimes marked hyperacidity, and are in fact, really cases of delayed hyperacidity. In the true achylia free HCL is absent in every specimen; the total acidity

is low and there is a marked hypermotility. In pernicious anemia one observes the typical features of a true achylia. (12) In nervous gastric affections one observes the various forms of hyper, hypochlorhydria or normal acidity. The hyperchlorhydrias present a rapid rise in acidity 100 or over with a normal motility. One frequently notes among these cases the so-called false achylia, with an absence of free HCl, at the end of an hour yet presenting a hyperacidity before or after this period. (13) In gall-bladder affections one observes a tendency to a lowered acidity and achylia, while in chronic appendicitis hyperacidity is usually observed. (14) While fractional analyses are of the greatest importance and usually present additional evidence in diagnoses, a study of our cases, together with the observations of Rehfuess, leads us to the conclusion that no pathognomonic curve exists which can be considered as absolutely distinctive of any gastric affection.

Some Observations on Sprue and Its Prevalence in the South.—Dr. SIDNEY K. SIMON of New Orleans stated that the clinical features of sprue were in general quite characteristic and, under ordinary circumstances, no difficulty should be experienced in differentiating the disease from other morbid conditions affecting the digestive tract. In a well advanced case, four cardinal groups of symptoms might be recognized: (1) An intensely red, desquamated, raw beef type of tongue, accompanied in most instances by a general ulcerative stomatitis. (2) A greatly inflated abdomen, doughy in consistency with enlarged intestinal coils often visible through the thinly stretched abdominal wall. (3) A chronic fermentative type of diarrhea characterized by unusually copious, pale yellow and foully smelling stools. (4) A progressive deterioration of strength, accompanied in most instances with marked pallor. Sixty-two cases in all were treated by Michel by a vaccine prepared in this manner and, of these, it was claimed that 49 were discharged cured, 12 were improved and only one died. From these figures, it would be seen that the vaccine treatment held out a promising field of therapy for the future. However, it had been stressed by Ashford, Michel, and others that in conjunction with the vaccine treatment, the usual dietetic regulations must be observed in order to obtain the best results.

Intubation Versus Tracheotomy in Laryngeal Diphtheria.—Dr. JOHN H. FOSTER of Houston, Tex., stated that there were four reasons for performing tracheotomy. (1) Greater assurance of relief. (2) Danger of intubation tube becoming stopped up by loosened membrane and patient asphyxiating. (3) Danger of patient coughing up the intubation tube and suffocating before any one capable of reintubating could be summoned. (4) Danger to the integrity of the larynx from pressure of the tube. The advocates of intubation advanced the following arguments: (1) Simplicity and ease of intubation. (2) Aftercare less troublesome than after tracheotomy. (3) Less shock. (4) No scar. (5) Shorter convalescence. (6) Parents did not demur at intubation as they did at any cutting operation. (7) Mortality lower, especially in view of the danger of sepsis and pneumonia following tracheotomy. (8) Less danger of permanent laryngeal stenosis. He did not think that the arguments in favor of tracheotomy were well taken or, at least, that they were sufficiently strong to establish tracheotomy as a routine procedure. His experience covered a period of fifteen years and embraced several hundred cases and he had never seen a death due to the tube becoming plugged up by membrane. In a fairly large number of cases he had seen membrane pushed down by the introduction of the tube and the patient's breathing became cut off. This was particularly apt to happen where the patient was too exhausted to cough vigorously and expel the membrane. It was then necessary to remove the tube and allow the loosened membrane to be coughed out.

Operative Treatment of Chronic Suppurative Otitis Media.—Dr. W. LIKELY SIMPSON of Memphis said that the objects to be attained in operating on a chronic suppurative otitis media were: (1) The prevention of complications as meningitis, sinus thrombosis, labyrinth suppuration, etc., or the relief of these conditions if they already existed. (2) The preservation and improvement of the hearing. (3) The cessation of the

discharge. The prevention of complications was the most important of these from the patient's standpoint. In chronic suppurative otitis media with the following complications the radical operation would be indicated and the modified radical contraindicated. (1) Facial paralysis. (2) Tuberculous infection. (3) Sinus involvement or sepsis from same. (4) Intracranial involvement. (5) Cases in which labyrinth suppuration was present might call for the radical operation, especially the subacute and the chronic types. The labyrinth operation usually should be done at the same time as the radical operation, the presence of sequestra, etc., helping in this decision. In the acute diffuse suppuration of the labyrinth there was certainly danger of setting up meningeal complications if the radical mastoid and labyrinth were done. (6) Circumscribed labyrinthitis. (7) Perilabyrinthitis.

Unrecognized Glaucoma and the General Practitioner's Responsibility.—Dr. HIRAM WOODS of Baltimore said that attention should be called to some of the details in the development of glaucoma, which the physician should know. They were: (1) The significance of frequent changes in glasses in persons over 50, especially in the direction of seeming myopia. Dangers of the optometry examination. (2) Misleading influence of the term "incipient cataract" for "lens striations." The latter often did not advance. If they did, uncomplicated progress was painless, and pain or injection meant something else. The cloudy appearance of the lens in glaucoma might be mistaken for cataract unless the ophthalmoscope was used. (3) The pain in progressive glaucoma was unlike that of eye strain. Often it was thought that to be neuralgic or rheumatic. These troubles were now known to be usually due to an infection focus. It was important to search for it. (4) Gastric disorders frequently occurred in progressing glaucoma. It was important to recognize the direction of cause and effect. (5) Recognition of the ocular injection of glaucoma as distinguished from that of conjunctival. A physician should know the differential diagnosis of conjunctivitis, keratitis, iritis and glaucoma or else let every red eye alone.

The Tonsils from a Clinical and Pathological Standpoint.—Drs. ELYRNE G. GILL and KENNETH D. GRAVES of Roanoke, Va., from their series of cases drew the following conclusions: (1) Discard the tonsils that harbor bacteria constantly. (2) There is a definite relationship between the pathology and symptomatology. (3) A history of well defined tonsillitis is a positive indication for tonsillectomy as our pathological investigations show that these tonsils are left in a state of chronic inflammation and serve as foci for infections just as a chronic appendix, abscessed tooth, chronic infection of gall-bladder, etc. (4) With the exercise of judgment and conservatism in the selection of cases for operation combined with thorough operative technique, good results can be expected from practically every tonsillectomy.

A Case of Extradural Abscess Complicating an Acute Left Frontal Sinusitis.—Dr. W. W. PERDUE of Mobile reported this case, from a study of which he drew the following conclusions: (1) Early drainage of the frontal sinus through the nose would possibly have averted the condition. (2) The infection advanced by way of the blood stream or lymphatics. (3) The rapid and alarming symptoms which appeared were those of a circumscribed purulent leptomeningitis, doubtless brought about by the dura mater becoming perforated in one or more places, thus allowing the pus to empty through. In some cases purulent meningitis can be cured by early drainage of the point of infection.

The Eye in Relation to the Ear, Nose, and Throat.—Drs. MEYER WIENER and H. W. LOEB of St. Louis drew the following conclusions: (1) Lesions of the eye and its adnexa occur far more frequently from pathological processes involving the nose and paranasal sinuses than is generally accepted. (2) A study of the minor processes would result in a more fruitful yield than that which has followed the interest in the exceptional and striking cases manifested up to the present time. (3) It is necessary to examine and to study in detail the nose and paranasal sinuses in all eye conditions for which they may be responsible, including conjunctivitis, lacrymal sac conditions, orbital cellulitis and abscess, corneal

ulceration, iritis and its associates, maturing cataract, retinal hemorrhage, retinal detachment, optic neuritis, ocular and retrobulbar, optic atrophy, glaucoma, reduction of vision, diminution of the field and functional disturbances not otherwise explained. (4) It is most important to examine for and to record any changes in the orbital or ocular tissues in all cases of acute or chronic suppurative processes involving the paranasal sinuses. (5) Persistent and intelligent study along these lines must bring about a solution of many of the vexing problems which have been uncovered by the casual study of the relation between the eye and the upper respiratory tract.

The Future Needs of Ophthalmology and Otolaryngology.—Dr. J. A. STUCKY of Lexington, Ky., stated that one of the most complex and important problems confronting the great profession of which we were a part was the food problem and its relation to impaired and distorted metabolism and perverted elimination. Amblyopia, diplopia, deafness, tinnitus aurium, as well as some pharyngeal and laryngeal conditions were frequently due to autointoxication of gastrointestinal origin, the direct action of the toxic substances being brought to the parts diseased from other parts of the body by way of the blood or lymph stream. He believed that what correct feeding and living of infants had done toward its health and the reduction of mortality, would have much to do with the prevention of many ophthalmic and otolaryngological diseases later in life. Our greatest work and ultimate goal must be in the prevention of disease. We were not to be made narrow by our specialty—we were not to be doctors only from the collar up; but as broad-minded aggressive men, qualified to do as well as it could be done, our part toward the protection, preservation and salvation of that part of our chosen field in ophthalmology and otolaryngology.

Eliminative Subjective Testing for Glasses.—Dr. CHARLES A. BAHN of New Orleans drew the following conclusions: (1) There can be but one lens combination which positively affords the best vision. (2) A retinoscopic approximation reduces the innumerable lens possibilities to a comparatively few. These can differ from the one best vision lens by containing first, too much or too little sphere; second, too much or too little cylinder; third, too much sphere with too little cylinder, or too little with too much cylinder; fourth, too great or small inclination of axis. (3) The innumerable lens possibilities can be reduced to one group and to one lens combination of that group, usually in three minutes, and in the manner described, by means of easily changeable test units of definite strength presented in front of more or less stationary tests. The first approximate test is the net retinoscopic finding and each successive approximate test is a closer approach to the one best vision lens and affords better vision than the preceding approximate test. (4) Definite strength test units in plus and minus, sphere and cylinder, depending on the visual acuity and definite strength axis units are employed for definite cylindrical corrections. (5) It is advisable that the patient compare each glass only with the preceding answering 'better or worse,' and employing any letter of the lowest readable line as a basis of comparison; and that not over ten successive comparisons be required of an eye in immediate succession; and that comparisons be required both on presentation and withdrawal of test units. (6) Test units which improve vision are incorporated in the trial frame or phorometer contents, forming, with the net retinoscopic finding or first approximate test, other approximate tests, each of which affords better vision than the preceding. (7) The last approximate test or final test represents the reduction of lens possibilities to one and is usually determined in three minutes. According to the patient's statement at least two times, the final test affords better vision than any other possible lens combination.

Alcoholic Insanity Increasing.—Cases of insanity from alcoholism have increased in the Cook County Psychopathic Hospital since prohibition went into effect, according to the quarterly report of Dr. James Whitney Hall. There was an increase of 33 per cent. in alcoholic cases in December, 1920, over the last officially "wet" December, and of 16 per cent. in November.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held November 23, 1920.

DR. LILIAN K. P. FARRAR IN THE CHAIR.

Two Cases of Interstitial Pregnancy.—Dr. S. DiPALMA reported these cases. He said that, judging from statistics, the occurrence of interstitial pregnancy was infrequent enough to warrant reporting these cases. The first patient was 29 years of age, II-para, Russian, admitted to the Harlem Hospital July 20, 1920. The last regular menstruation was May 20, 1920. The present illness began with cramps in the lower abdomen five hours before admission. The patient vomited greenish fluid, became pale and gradually weaker. Laparotomy was performed shortly after admission. Upon opening the peritoneum a large quantity of blood escaped. On exploration of the uterus and adnexa the right tube was not found. The left tube was normal. A moderate number of small follicular cysts were present in both ovaries. The body of the uterus was slightly enlarged and the seat of multiple small fibroids. On the upper aspect of the fundus, about 1 cm. from the entrance of the Fallopian tube, a rupture was found which was roughly circular and about $\frac{1}{2}$ cm. in diameter, through which blood oozed freely. The tube was removed. The embryo was not found. The patient was discharged cured on the sixteenth day. The pathologist's report stated that microscopic section through the cornu showed typical chorionic villi. The diagnosis was interstitial pregnancy.

The second case was in a patient 32 years of age, VII-para, white, and a native of the United States. She was admitted to the Harlem Hospital October 16, 1920, with the history that all her labors had been difficult and in several instances were complicated by fever. The last pregnancy resulted in a six weeks abortion. She was not curetted. The menstrual period was two weeks overdue. Her present illness began at 10 P.M., the night before admission, with pains in the lower abdomen, vomiting, and, though she did not faint, she gradually went into shock. A diagnosis of ruptured extrauterine pregnancy was made by Dr. Brodhead. On opening the peritoneum dark blood escaped; the peritoneal cavity was filled with blood and blood clots. The uterus was found slightly enlarged; the left cornu had a small rupture superiorly, which was roughly circular and about 5 cm. in diameter, through which there was moderate bleeding. Both adnexa, with the exception of a follicular cystic ovary, were normal. The left cornu and adnexa were removed. The embryo was looked for but not found. The patient died of sepsis on the eighth day. The blood culture showed anaerobic hemolytic streptococcus. The post mortem examination revealed no peritonitis and no hemorrhage. The pathologist's report stated that microscopic section of the enlarged middle portion of the tube showed a dilated tube, the lumen of which was filled with masses of decidua-like, deep-staining cells—syncytial cells—and chorionic villi associated with moderate hemorrhage. The diagnosis was interstitial ectopic gestation.

The important features connected with these cases were: (1) Previous history of abortion, or pregnancy complicated by fever. (2) Early rupture. (3) Extensive peritoneal hemorrhage. (4) Finding of normal adnexa. These features were important because they tended to explain the course and the cause of interstitial ectopic pregnancy. In reviewing the literature, where a previous history of the patient was given, in most instances a record of previous abortions or uterine infection was obtained. The writer's opinion corresponded with that of Farrar in ascribing the cause, except in rare instances, to a previous low grade inflammation of the uterus. The inflammation being severe enough to affect only a portion of the interstitial tube damaged its lumen to such an extent as to prevent the ovum entering the uterine cavity, yet not enough to hinder the entrance of the spermatozoa. In the speaker's opinion the time of rupture and the amount of intraperitoneal hemorrhage depended upon the site of the implantation of the

fertilized ovum and the relation of its chorion frondosum to nearby blood vessels. If implantation occurred near the uterine end, the possibility of an early abortion in the uterus would be apparent; if at the isthmic end, by the trophoblastic action of the chorion frondosum in a place of least resistance, rupture would take place early, generally into the peritoneal cavity, occasionally in the folds of the broad ligament, depending upon whether the attachment of the ovum was on the superior or inferior aspect of the tubal lumen. The hemorrhage from arterioles usually present in this location would be extensive. If implantation should take place between the uterine and isthmic ends, the thickness of the musculature of the fundus and of the uterine wall being considerable in this location, it would seem probable that before rupturing, the pregnant sac would attain a large size, and the uterine rupture would be attended by a very extensive hemorrhage from hypertrophied blood vessels if these were involved.

A Delivery by Cesarean Section after a Previous Normal Delivery.—Dr. EDWARD C. LYON reported this case. He said that they were familiar with the type of case in which the first delivery was difficult and subsequent ones normal, and also with the rarer type of case in which the first delivery was normal and succeeding ones required interference (due to the first child being small, or the head settling into the inlet early in pregnancy and being more readily moulded). The case to be reported did not fall into either of these groups, for the first child was delivered by high forceps; the second normally, and the third by cesarean section, and yet the cesarean baby was smaller than the one delivered normally. The patient was white, born in Austria, and gave a negative history. The physical examination showed no deformities. Fortunately the three deliveries were in hospitals and accurate data were obtainable. In the sixth month of her second pregnancy the pelvic measurements were normal although the external conjugate was almost borderline, being 18.50 cm. The sacral promontory was not felt. When admitted to the Prenatal Clinic of the Woman's Hospital in the sixth month of her third pregnancy, May 18, 1920, the measurements were practically the same as before. The sacral promontory was not felt at this time though examined for. The chart showed a note stating that there was "some sacral flattening." The patient was admitted to the hospital at term, two hours before pains began. The head was unengaged (L.O.A.). The first stage lasted seven hours. The membranes were ruptured artificially at the beginning of the second stage. After six hours of hard labor the head was still unengaged and showed no tendency to pass the promontory. There was a large caput with marked overriding, and apparently good flexion. The sacral promontory could be reached. The diagonal conjugate was found to be 11.50 cm., making the true conjugate at least 9.50 cm. A cesarean section was performed and a child weighing 7 pounds 11 ounces delivered in good condition. This baby weighed six ounces less than the one delivered without interference, in the same hospital two years before, and was normal in every respect. The mother and baby were discharged in good condition on the fifteenth day. Examination in the Follow-up Clinic, one month after delivery, showed the promontory large, irregular, and projecting well forward into the inlet. The diagonal conjugate was again measured and found to be the same as before. The case was reported without comment as Dr. Lyon said he had no explanation to offer as to why such difficulty was encountered.

Dr. DOUGLAS BISSELL said Dr. DiPalma's case was identical with one, the only one of its kind he had had in his practice. It was a type of interstitial pregnancy which was the exception and not the rule. The rule in interstitial pregnancy was that the embryo developed to considerable size before rupturing, and that seemed logical because the ovum, when implanted in the uterine portion, had the uterine wall to protect it. When the case to which he was referring came under his care the woman was conscious but not exsanguinated, and with an almost imperceptible pulse. The patient was brought to the hospital with no history, but as the abdomen was greatly distended by fluid and the cause seemed self-evident, the abdomen was opened immediately. On opening the abdomen 500 c.c.

of salt solution was administered intravenously. At operation a great quantity of blood was removed from the abdominal cavity. The examination of the tubes and ovaries showed them to be normal, but near the juncture of the left tube and uterus a small rent was seen in the uterine wall, which he at once determined was the rupture of the interstitial pregnancy. They were more fortunate than Dr. DiPalma for in examining the clots the embryo was found, which the pathologist determined to be a five weeks gestation. This was the only case of interstitial pregnancy he had had, and he related it because he thought all such cases should be put on record.

Dr. GEORGE GRAY WARD, Jr., cited a case of interstitial pregnancy that came under his observation some years ago, which had all the characteristics of this terrible catastrophe. The patient was about 4½ months pregnant and was all right so far as she knew. She had severe pain during the night and a physician diagnosed ectopic pregnancy. He telephoned to the Post-Graduate Hospital that he was bringing her in an ambulance. On the way the ambulance collided with a bus, and the patient was pretty well shaken up and immediately went into profound shock. When she arrived at the hospital she was unconscious and presented all the signs of severe internal hemorrhage. She was taken at once to the operating room and the abdomen opened. The abdomen was filled with blood and an interstitial pregnancy was found. The entire horn of the uterus was blown off. This patient made a good recovery. Dr. Ward said that he also, like Dr. Bissell, cited this case for the reason that he thought all such cases should be reported, and because they constituted a class of cases in which delay was not allowable. If there was any suspicion of interstitial pregnancy, he believed the patient should be operated upon at once.

Dr. HERMANN GRAD said that in the series of 50 cases of ectopic gestation which he had reported at the last meeting of this Section, interstitial pregnancy occurred twice, and both types of rupture were exemplified. There was one in which there was a small opening in the uterus, and in the other the whole horn of the uterus was blown off and the hemorrhage was alarming. In this case the question came up whether or not a hysterectomy should be done. The patient was in no condition to stand an extensive operation, so he simply stopped the hemorrhage by sewing up the rent in the uterus. In the 50 cases there were two cases of ectopic pregnancy in which hysterectomy was done because of complicating conditions. Both of these cases made stormy recoveries. It seemed that it was not advisable to do a large amount of work in these greatly shocked cases.

Dr. FARRAR stated that in the only case of interstitial pregnancy that she had had, she opened the abdomen thinking she was dealing with a tubal pregnancy, and found an interstitial pregnancy that had not ruptured through. She was able to curette out the contents without the necessity of removing the tube that contained the embryo. She was inclined to think that interstitial pregnancy was more common than statistics would lead one to believe, as a case of this variety of ectopic gestation might rupture into the uterus and be mistaken for an intrauterine pregnancy and subsequent abortion.

X-Ray Changes in Two Cases of Fibromyoma of the Uterus, and One Case of Carcinoma of the Breast.—Dr. R. E. HERENDIEN reported these cases. He stated that the first patient, 58 years of age, was referred to the x-ray department of the Memorial Hospital for radiation of a large myoma. She complained of inability to void urine, obstinate constipation, nausea, and vomiting. A diagnosis was made of fibromyoma of the uterus holding the bladder up in front of it. The patient was given a series of x-ray treatments beginning Jan. 1, 1920. Three areas were exposed over the lower anterior surface of the abdomen at weekly intervals, each getting an exposure every three weeks. The dosage was 9—9½-inch spark gap, 4 milliamperes, at a distance of 8 inches for 4 minutes. Later this dose was increased. The patient was not operated upon because of a bronchitis and a heart condition, the heart being 1½ inches below the normal line and enlarged to the left. The second patient was 37 years of age, and was referred to the x-ray department in

April, 1920, for treatment of a large myoma. The tumor was situated in the lower abdomen chiefly on the right side. The patient complained of menorrhagia, weakness, nausea, eructations. She had marked anemia, the hemoglobin being between 30 and 40 per cent. and she was not considered operable on that account. She was given a series of twelve treatments, using the minimum skin toleration dose. This dose was gradually increased, three areas over the lower abdomen being covered, as in the preceding case. The patient now presented evidence of being an operable case.

The third patient was a woman 82 years of age with a carcinoma of the breast, which was inoperable because of her age. The lesion was large, ulcerating, and extended high in the mid-axillary line and to within one or two inches of the right border of the sternum. It was four to five inches in diameter, foul smelling, and there was considerable discharge. Treatments were begun in March, 1920, the entire right breast being covered, including the supraclavicular region and the right axilla. Eight treatments, in all, were given, and at the present time the ulceration was entirely healed. She had some axillary involvement, and a faint indefinite feeling of induration in the right axilla. There were no well marked glandular enlargements and this indefinite feeling of induration might be the result of radiation. This patient, in the speaker's opinion, presented evidence of the results that might be obtained in some apparently hopeless cases. When she first came under observation the lesion was so extensive that it scarcely seemed worth while attempting to do anything for her.

Dr. LEE asked whether in the second case of myoma the hemorrhage had ceased to any extent.

Dr. HERENDEN replied that it had decreased considerably.

Dr. GEORGE GRAY WARD, Jr., asked how much the fibroids had been decreased in size.

Dr. HERENDEN said that in the second case the fibroid had been reduced easily one-half. Perhaps some of the members of the staff of the Woman's Hospital who had examined the woman before she was treated could tell more exactly.

Dr. WARD asked whether the difficulty in urination in the first case had been relieved.

Dr. HERENDEN replied that the difficulty in voiding had ceased, but there had been no marked diminution in the size of the tumor.

Dr. FARRAR stated that Dr. Bissell had seen the first case and advised against operation on account of the bronchitis and cardiac condition. The tumor corresponded to the size of a five months pregnancy. Radium was introduced and there was considerable contraction of the growth. The patient had had great difficulty in emptying her bladder and had to be catheterized before she came to the hospital. This trouble disappeared after the use of radium, but Dr. Ward suggested that she be sent to the x-ray department to see what could be done to further contract the tumor.

Dr. LEROY BROWN asked Dr. Herenden if he had had any opportunity to observe the effect of treatment on the temperature curve. He had seen the temperature curve go up for two weeks after treatment and there was a very profuse uterine discharge.

Dr. HERENDEN replied that as far as he knew there was no change in the temperature. By questioning the patients they found that during the first treatments the bleeding was entirely controlled, but there was a great deal of seropurulent discharge.

Dr. BROWN said he asked the question because he had referred a case to Dr. Herenden and the results had been most gratifying. When the patient came into the hospital her hemoglobin was between 30 and 35 per cent., and she was having profuse uterine hemorrhages. A chronic cardiac condition absolutely precluded surgery. The uterine myoma extended to within two fingers of the umbilicus. The final result was that the tumor had contracted to the size of a three months pregnant uterus. Dr. Brown said he had asked about the discharge because in his x-ray treatment of this patient she developed a profuse mucopurulent discharge with temperature ranging from 102° to 104° F., together with an alarming pulse condition. It was found necessary to discontinue the

x-ray treatments. The patient's temperature gradually subsided as also did the mucopurulent discharge. Her condition steadily improved, hemorrhages ceased, and after the giving of two transfusions of blood of 500 c.c. each the patient was discharged with a hemoglobin of 45 per cent. and in excellent condition. The result was most satisfactory.

Dr. HERENDEN said the fact that the first patient was given a higher dosage was because of the thickness of the abdominal walls. She was a heavy woman and the amount of radiation available in such a patient was considerably less than in a normal person.

Dr. HERBERT L. CHASE, after examining the patient, reported that the uterus had contracted at least one-half since the time he examined her before the treatment. The tumor was practically up to the umbilicus; it was now $3\frac{1}{2}$ fingers above the pelvic brim.

Photographs of a Case of Large Hematoma of the Vulva.—Dr. LEROY BROWN showed two exquisitely colored photographs by Dr. Kilmer, which had never been shown before except at a conference at the Woman's Hospital. They represented an unusually large hematoma of the vulva following normal labor in a primipara. No instruments were used, and $\frac{1}{2}$ c.c. of pituitrin was given only in the first stage of labor when it could not have been a factor in causing this condition. The hematoma was so extensive that it occluded the vagina and pushed back the urethra so that it was almost impossible to catheterize the patient. Six hundred grams (1 $\frac{1}{4}$ pounds) of blood clot was removed, and a great deal was left behind adherent to the tissues. The seat of the original tear was in the left lateral wall of the vagina. The perineum was not visibly torn. While small hematomas were common such large hematomas were rare. In 20,000 cases reported by Dr. Lee there were five cases of large hematoma. The treatment of course was well recognized. The hematoma was incised, the blood clot removed, a few rough sutures inserted to hold the fascial layers together. The vagina was packed with gauze. A second operation would be done if necessary.

Dr. LEE asked how long after labor this hematoma appeared.

Dr. BROWN replied that this was Dr. Bridge's case. He left the patient one hour after labor. At the end of two hours she complained of a tingling sensation and pain. Examination showed a tumor, and at the end of two hours it had increased alarmingly.

An Analysis of Two Hundred Gynecological Cases Treated with Radium at the Woman's Hospital in the State of New York.—Dr. E. W. TITUS of Washington, formerly Resident Gynecologist of the Woman's Hospital, presented this study. He stated that 230 milligrams of radium element were put at the disposal of the Surgical Staff of the Woman's Hospital, in February, 1919. From that date to August, 1920, a period of eighteen months, it had been used in a total of 201 cases. The results obtained corresponded to those of others. In this series there were 95 cases of carcinoma of the uterus, 86 of the cervix, and nine of the fundus. Of the cases of carcinoma of the cervix there were 55 living, of which 24 were under six months after radiation. All but seven of these were too recent to report, were healed, and were free from symptoms. Twenty-four others were between six and twelve months after radiation and seven between twelve and eighteen months. Of these 86 cases of carcinoma of the cervix, 31 had died, 16 less than six months after radiation; 9 died between six and twelve months after radiation; six died between twelve and eighteen months after radiation. Two deaths were due to distant metastases, one to the lung and one to the liver. Another death two months after radiation was due to pneumonia, probably influenzal. As to symptomatic results, 64 per cent. of those complaining of pain had been relieved of it; in three per cent. of those complaining of pain, pain was increased. Hemorrhage and leucorrhoea had been checked in all but two cases. There was an improvement in general health with the disappearance of symptoms. There was a recurrence of hemorrhage in six cases after four to six months. The only sequelae sufficiently severe to demand treatment was occasional bladder and rectal irritation. Two fistulae resulted, one vesicovaginal and one rectovaginal. Seven cases of advanced car-

cinoma were living and free from symptoms, clinically cured a year or more after radiation. Four of these nine cases of carcinoma of the fundus had a complete hysterectomy. One had preoperative and postoperative radiation. All were clinically cured except two. Of carcinoma of the vagina there were five cases, one primary and four recurrent after hysterectomy; two were living, one clinically cured after twelve months, and one after six months. Three had died, one two months and two six months after radiation. There were two cases of cancer of the vulva, both living. One improved and later showed extension; the other was too recent to report. There were three cases of carcinoma of the breast, treated after radical removal. One died seven months later of extension to the mediastinum; the other two were free from recurrence after one year. In carcinoma of the urethra and bladder the results were not so good. There was relief of hematuria, but little effect was produced on the lesion. There were five cases of carcinoma of the rectum, all improved after radiation. Four were living, one six months and three over one year after radiation. One died after resection of the sigmoid from the shock of the operation. Of the non-malignant cases 44, 15 under and 29 over forty years of age, were cases of myoma uteri. The hemorrhage was controlled and there was a reduction in the size of the tumor in all. In two instances the tumor disappeared. There were 39 cases of menorrhagia and metrorrhagia under forty years of age, in which there was a control of hemorrhage in all but three cases. In these cases the dosage was governed by the age of the patient. In young women they had used small doses repeated if necessary. A six hundred milligram-hour application was considered safe. Under this dosage menstruation usually appeared normally in two or three months. With larger doses it might continue irregularly for two or three months and then cease. In one case following a 200 milligram-hour exposure for chronic endocervicitis, conception took place eight months later. Abortion took place at the third month. (Hydatid mole.) All cases in which leucorrhea was present previous to radiation were cured by it. There was a watery discharge for one or two weeks following radiation. Three cases receiving 2400 milligram-hour exposures suffered severe menopause symptoms, and 13 cases which received from 1500 to 2100 milligram-hour exposures suffered from mild menopause symptoms. In eight cases with 1200 to 1800 milligram-hour exposures the results were excellent. In carcinoma of the cervix radium had proven itself (1) the most dependable palliative in advanced cases; (2) a most reliable adjunct to surgery in the operable cases; (3) capable of relieving pain and prolonging life. In properly selected cases of myoma uteri it was a strong rival of surgery. In large tumors requiring operation it would control hemorrhage and allow delay until there was an improvement in health. In intractable menorrhagia of young women it had solved a difficult problem. It could be so applied that the reproductive function was not interfered with. Mortality and morbidity in gynecological practice had been materially reduced by the use of radium. Its power to prolong life made it an economic factor to the State. Radium might eventually remove carcinoma of the cervix from the domain of surgery. Radium was contraindicated in pedunculated subserous tumors and in myomata of young women than could be removed by myomectomy. Myoma associated with pelvic inflammatory disease should not be radiated.

Myomectomy Versus Radium and X-Ray in the Treatment of Fibroid Tumors in Women Under Forty Years of Age.—Dr. HIRAM N. VINEBERG read this paper. (See page 91.)

Dr. GEORGE GRAY WARD, Jr., congratulated Dr. Titus on his painstaking analysis of the records of the Woman's Hospital, and stated that he could bear witness to the care and accuracy with which he had drawn his deductions from these records. Dr. Titus had had the opportunity of seeing the results he reported in the follow-up clinic, so he considered his conclusions of value. Radium had been available at the Woman's Hospital for only eighteen months, hence the results, so far as the carcinoma cases were concerned, were only of tentative value, owing to the shortness of time these patients had been under observation. Dr. Ward empha-

sized the importance of making a thorough examination of the patient at the time the radium was being applied. At the Woman's Hospital they were using an anesthetic and made both an abdominal and a pelvic examination in order to recognize any complications that might exist. Often one's opinion might be changed after this examination under anesthesia. A diagnostic curettage was indicated in all cases with metrorrhagia or menorrhagia, as one might thus discover an unsuspected polyp, and it was known also that a fibroid might undergo malignant degeneration. As an after effect of the treatment there might be nausea and vomiting, though this was usually transient and need not be taken into consideration. As to the leucorrhea that had been reported as very troublesome by other observers, at the Woman's Hospital they had questioned the patients, examined them, and made careful records, and they could not note the excessive amount of leucorrhea which others seemed to have noted. He had talked to Dr. Viol of the Radium Chemical Company about this, and he thought it might be due to the extra distance gained by the use of the 1 mm. brass filter. It was not only that the beta rays were cut off, but there was an increase in the distance of 1 mm. in addition to the silver capsule holding the radium, and in this work 1 mm. made a difference which was of definite value. They had come to prefer two tubes of 50 milligrams placed in the uterus in tandem, because in this way a greater surface could be covered, which was an important point in a uterus that was enlarged, and they had found that they obtained better results when the radium was used in this manner. It was an interesting question as to whether operation should be combined with radium in cancer cases. He believed that in cases that were operable, or might become operable, it was safer to operate than to rely upon radium alone. Dr. Clark of Philadelphia and some others believed operation was unnecessary. He had had one early case of carcinoma of the cervix in which after the use of radium he did a radical Wertheim operation and had the entire specimen examined microscopically, and it showed no malignant disease. That case ought to show a permanent cure, but he had two other cases in which all evidences of the disease had disappeared after radium and in which the Wertheim operation disclosed the disease outside and beyond the uterus. One could not be sure that there was not involvement beyond the uterus in any case, so he thought it gave the patient a better chance if an operation was performed after radium had been used. Reuben Peterson reported in his series of Wertheim cases under observation over five years that 18 out of 47 cases were alive, approximately 40 per cent. If one could obtain such a percentage of radical cures after five years with the Wertheim operation he was very fortunate, and we should not cast aside any method that could produce such results. However, five years was not a sufficiently long period to enable one to say that the cure was permanent. Dr. Ward cited a case in which he did a Wertheim operation and the patient remained cured for five years, but in the fifth year she developed metastases in the bones of the pelvis and died thereof. Therefore, he believed that radium combined with radical operation where possible should give us the best results. He summarized the lessons from this report as follows: "We have three very valuable aids in combating cancer. Operation is very valuable as shown by Peterson. The x-ray is a valuable aid, and so also is radium. In employing these three valuable aids we must learn to individualize our cases, using sometimes one, sometimes another, and also in combination, according to the conditions which are present." Dr. Ward said he was heartily in accord with Dr. Vineberg's statement regarding myomectomy. In young women myomectomy was the proper procedure, and it should always be remembered that if a young woman had a small fibroid that was overlooked at the operation of myomectomy and it subsequently enlarged and caused trouble, still one had radium to fall back upon.

Dr. LEROY BROWN agreed with Dr. Vineberg and Dr. Ward with reference to the treatment of uterine fibroids. He was opposed to their treatment with radium or the x-ray. Of course, they all favored the treatment of hemorrhage with radium or x-ray under circumstances where they felt it would not be wise to submit the patient to surgery. Dr. Brown presented a chart

summarizing the results of a study of 1,500 consecutive cases of myoma uteri operated on at the Woman's Hospital from 1910 to 1917 (*American Journal of Obstetrics and Diseases of Women and Children*, lxxviii, 3, 1918) showing the many coincident pathological conditions associated with these cases, and an operative mortality of 1.86 per cent. Dr. Broun said his object in presenting the chart was to show that the majority of cases referred to the roentgenologist for treatment were sent by the general practitioner who had not had impressed upon him the fact that other conditions might coexist with a fibroid which precluded the use of the x-ray or radium for these cases. If they excluded the cases of carcinoma of the cervix and of pregnancy with fibroids, it would be seen that in the 1,500 cases tabulated 691 cases had some complication which precluded the use of x-ray or radium, and which, on the other hand, made it advisable to do a surgical operation. It was impossible to pick out these cases having complications; we did not know positively what other conditions were present, in addition to the fibroid, which made the general use of the x-ray and radium dangerous. In the cases that they felt were relatively uncomplicated and which were poor surgical risks they adopted the x-ray and radium by choice. As to the question whether the treatment of hemorrhage by radium necessarily abated the menstrual function, he had been under the impression that after a year or two the menstrual function returned. However, he heartily agreed with Dr. Vineberg that it was more conservative to do a myomectomy to prevent the fibroid from becoming large, for the larger the tumor the more likely was it that other pathological conditions would coexist.

Dr. HOWARD C. TAYLOR said there was little in the two papers with which he disagreed. With Dr. Vineberg he agreed entirely that a myomectomy involved a small risk and a small chance of return, and it could be done for extensive growths if necessary. He preferred to do a myomectomy to using radium in young women in most cases. With one statement he disagreed absolutely and that was that the treatment with radium was without risk. That was far from being true. He had seen one death result from radium treatment. That there was a certain amount of risk from radium must be borne in mind. There was a definite risk in overlooking malignant conditions and also in overlooking conditions that made the use of radium unsafe. This was true no matter how carefully an examination was made, even if made under an anesthetic. Dr. Taylor said the work done at the Woman's Hospital tallied almost exactly with his work and with his results. One thing he thought we should have was a standardized nomenclature for the dosage in the use of radium. One man spoke of so many milligrams, another of so many millicuries, and another of so much emanation. This difference in nomenclature was very confusing. At the Woman's Hospital the unit they were using was 100 milligrams, which was the amount used by most gynecologists throughout the country, and the description of the dosage and screening as given by these men were more valuable to him than when other terms were used. If we were going to understand the use of radium we must come to a common language. As to radium in fibroids, he had been employing smaller quantities than Dr. Titus reported were used at the Woman's Hospital, but he had been using the same screening. In regard to a discharge following radium treatment which Dr. Ward said their patients did not have, he thought this was not a matter of great import, because it disappeared in four or five weeks, and therefore could be ignored. Most of his cases, however, did have a watery discharge for a time after the use of radium and he always warned patients against it in advance. As to the use of radium in carcinoma of the cervix, he did not believe that we were going to give up operating in malignant conditions of the cervix. In treating a case of carcinoma of the cervix he gave the patient an anesthetic in practically every case to apply the radium. Under the anesthetic the radium could be placed in the most advantageous position, a piece of the uterus could be obtained for microscopic examination, and the extent of the disease with its bearing on operability could be determined. If the case were operable the operation should be performed in ten days or two weeks. The use of radium would diminish

the chance of implantation of metastases and also lessen the chance of infection by cleaning up the cervix as no other agent in his experience would do. The difficulty of the operation was not materially increased by the use of radium. If the operation were done too early there might be some increased risk of infection due to diminished resistance of the tissues.

Dr. EDWARD WALLACE LEE asked whether the anesthetic was repeated every time the radium was applied. If you repeated the radium treatment in six weeks or two months, would a specimen be taken each time by a punch or curette to determine what the diagnosis was after the first or second treatment. Dr. Lee asked Dr. Titus whether in the series of cases in which the detailed statistics were given the hemorrhage had been temporarily increased after the application of radium. He said he asked that because he had seen a number of cases in which the hemorrhage was increased after the application of radium, and he felt he could not trust to the continued use of radium and immediately resorted to operation. Dr. Taylor brought up a good point when he spoke of the confusing nomenclature in regard to radium emanations, milligram hours, etc. It would seem that we were coming to the time when the use of radium should be in the hands of the specialist. If the ordinary surgeon or the ordinary gynecologist thought he saw an indication for the use of radium or the x-rays he had to turn the patient over to a man who had that in charge. It was just like a drug, we might write the prescription but the druggist filled it, and in the same way we might prescribe radium and the patient went to the radium specialist for treatment, and we should be assured that the radium man knew his business in all the details.

Dr. BAILEY stated that the terms used in connection with the dosage were easy to understand. A millicurie was absolutely in balance with one milligram—they were exact equivalents. In reference to Dr. Herendeen's report of two cases of fibromyoma, the second case was a most excellent result from x-ray treatment. This tumor extended 8 cm. above the symphysis, and was perhaps as large as an orange. It was now one-third its former size. The first case had a large dose of radium and the result could hardly be attributed entirely to the x-ray. There were two different treatments with radium, one being 2,400 milligram-hours and one 1,200 milligram-hours, but with quite different filters from those he was using or those used by Dr. Clark. He had been using a platinum applicator which cut off all the beta rays and part of the gamma rays. This patient received three or four times the dose of radium he would give, so he thought the results could hardly be attributed to the x-ray. Dr. Bailey expressed surprise that more had not been said about the bad results of the treatment. His experience was that cases returned a number of years later showing bad effects, and therefore it was better to use a smaller amount of radium. The effect of the radium was to cause a fibroids which constricted the nerve ends. Even in large fibroids he used a smaller dose than that mentioned by Dr. Titus. It was evident that Dr. Titus's dose for fibroid was larger than his largest dose in cancer of the uterus. The correction, of course, had to be made for the platinum and brass filters. He hoped to get as good results and save one-half the radium by substituting brass for platinum, following the recent work of Dr. Failla on the penetration of the rays through different metals. The cancer problem was very intricate and the most unusual things happened. He had had two cases that after the use of radium had Wertheim operations and no cancer was found, and these patients died within a year or a year and a half. Another case in which the parametrium was filled with cancer cells, which, however, showed signs of the action of radium, was alive and apparently well after a year and a half, so there was a great question as to how we could take these results. He had come to the conclusion that operable cases should have small doses of radium and be operated upon. As to the fibroids, Dr. Broun's presentation was very illuminating. It showed a mortality of only 1.86 per cent. That might be lessened by radium, but the patients treated by radium in most instances still had some remains of their fibroids and there might be a marked morbidity among these. Operable cases of fibroid might be treated by radium only

when it was possible to use cross-fire. Where small doses only were available the operable case should not be treated by radium alone but by radium followed by operation. Of the fibroid cases, about 50 per cent. fell into the class suitable for radium treatment. In regard to the myopathic hemorrhage cases, they should have the amount of radium that allowed the woman to menstruate again. It was true that with a proper dose of radium they did menstruate and they even became pregnant. However, adjusting the dose to cure the condition and yet have a return to normal menstrual life a year later was a theoretical consideration that did not work out in practice with any degree of regularity.

Dr. DOUGLAS BISSELL asked if x-ray was equally applicable to pedunculated and sessile fibroid tumors, and whether radium could be applied successfully to pedunculated fibroids. He made this inquiry because some authors claimed that pedunculated fibroids were not benefited by the application of radium, and that there was at times much difficulty in differentiating between pedunculated and sessile fibroid tumors. Dr. Bissell cited two interesting cases which recently came under his observation, in neither of which could the diagnosis of pedunculated fibroid be readily made. In the first case, a woman married three months, examination revealed a solid mass in the abdomen extending to the diaphragm. The uterus could not be differentiated from the tumor. He was of the opinion that he had to deal with a large fibroid of the uterus complicating an early pregnancy. On opening the abdomen he found a ten-pound pedunculated fibroid attached to the fundus of the uterus by a pedicle one inch in diameter, and was able to remove the tumor without interfering with the existing pregnancy in the uterus otherwise normal. The second instance was encountered that morning. Examination showed two large tumors each as large as a grape fruit. One tumor extended to the region of the liver and the other occupied the true pelvic cavity, reaching as high as the navel. The first tumor he considered either a pedunculated fibroid or a thick-walled ovarian cyst. The second tumor he thought was a sessile fibroid of the corpus. On opening the abdomen he found the first tumor to be a pedunculated fibroid with a pedicle arising from the left side of the uterus, the tumor having been forced over to the right side of the uterus, and the second tumor was also a pedunculated fibroid with its pedicle rising from the right side of the uterus. This tumor was fixed in the pelvis and prevented all possibility of determining its true character. The uterine corpus was extremely small, the cavity measuring only one inch. The situation of the corpus was in the neighborhood of the coccyx, and therefore a very considerable distance from the fibroid tumors. This patient had been advised by a competent gynecologist in a neighboring state to have radium applied through the uterine cavity, and advised against operation. Dr. Bissell stated that after examining the specimen it was his opinion that the influence of radium through the uterine cavity would have been nil, because of the great distance between the uterine cavity and the tumors.

Dr. TITUS said that in regard to the question of increased hemorrhage, he did not recall any case in which the amount of hemorrhage was increased. He recalled a few patients who said they had quite a little hemorrhage following the treatment, but the first menstrual period was not more excessive than previously.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

OREGON STATE BOARD OF MEDICAL EXAMINERS.

July 6, 7, 8, 1920.

(Concluded from page 41.)

GYNECOLOGY.

1. Give the nerve and blood supply of the uterus.
2. What muscles constitute the pelvic floor.
3. Why do some women with retro displacements suffer, while others are free from symptoms of any kind?
4. Give the diagnosis and treatment of acute salpingitis.

5. Give the technique of Watkins' operation for pro-cidentia.

6. Give the diagnosis and treatment of cancer of the ovaries.

8. Discuss briefly the causes of sterility.

SURGERY.

1. Give symptoms, diagnosis and treatment of gall-stones.

2. Give cardinal rules for (a) treatment of recent wounds; (b) treatment of infected wounds.

3. Give symptoms and diagnosis of malignancy of the mammary gland; Give treatment in detail.

4. You are called at midnight to see a man of thirty, taken with severe abdominal pains; he has vomited once or twice and has most pain below the navel—with general tenderness over the entire abdomen; temperature 100°, and pulse 90, respiration 20. What would you do first and how would you differentiate between appendicitis, intestinal colic, and intestinal obstruction? Give treatment in brief.

5. Give the technique of tendon transplantation.

6. (a) Under what conditions may an abdominal wound be closed without drainage? (b) Give reasons for draining an abdominal wound and tell what kind of a drain should be used.

7. Give diagnosis and treatment of osteomyelitis.

8. Give symptoms, diagnosis and treatment of Pott's disease.

EYE.

1. (a) Name the diseases that the findings of the retina aid in diagnosis; (b) Define trachoma and glaucoma.

2. (a) How is the cornea nourished and what is its function? (b) Describe the technique for removing a piece of steel from the cornea. Name after-results that may follow.

3. (a) What is the iris and its function? (b) What do you mean by the fundus of the eye? (c) What is the macula of the eye?

4. (a) Give symptoms, diagnosis of ophthalmia neonatorum. (b) Name the sequelæ of improper treatment.

EAR.

1. (a) Give the symptoms of acute otitis media. (b) Why is the pain at times referred to the teeth?

2. Where should the membrana tympani be opened in doing paracentesis, and why?

3. What is the danger in doing a mastoidotomy?

4. Differentiate the diagnosis of impacted cerumen and furunculosis of the auditory canal.

ANSWERS.

GYNECOLOGY.

1. *The nerve supply of the uterus:*—From the sympathetic system (hypogastric, renal, spermatic and aortic plexuses), and from the second, third, and fourth sacral nerves.

The arteries which supply the uterus are the uterine and ovarian.

2. *The muscles which constitute the pelvic floor, are:*—Levator ani, coccygeus, sphincter ani, transversus perinei, and constrictor vaginae.

3. "There is some difference of opinion as to the part played by a backward displacement of the uterus in the causation of symptoms, which are so often found accompanying the condition. Some hold that retroversion *per se* does not produce troublesome symptoms; they state that normally the uterus is constantly changing its position, according to changes in the condition of the bladder and bowel, and that it may, when turned to the back, trouble the woman as little as when turned to the front. They state that the symptoms which are so often found along with retroversion—*e.g.* pain and weakness in the back, menorrhagia, etc.—are due to accompanying inflammations outside the uterus, inflammations in the uterus itself, subinvolution, or some prolapse of the organ."—(Webster's *Diseases of Women*.)

4. *SALPINGITIS. Diagnosis:* A dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenor-

rhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesions; there may be an intermittent expulsion of pus accompanied and preceded by a burning pelvic pain.

Treatment: Rest in bed, hot vaginal douches, saline purgatives, liquid diet, morphine (if necessary) for pain, removal of pathological conditions and complications; radical operation (salpingectomy, or salpingo-oophorectomy) may be necessary.

5. **Watkin's operation for procidentia:**—"This operation is specially adapted to cases of extensive cystocele and uterine prolapse in women who have passed the menopause or who have been rendered sterile by operation. The object is to bring the uterus down through the anterior vaginal cul-de-sac and to pocket it between the anterior vaginal wall and bladder. In this way it serves the double purpose of supporting the cystocele and preventing descent of the uterus. The patient being placed in the lithotomy position, the cervix is grasped with a volsella and a crescentic incision made anteriorly at the cervicovaginal junction. A second incision is carried from this along the median line of the anterior vaginal wall to within an inch or less of the meatus urinarius. This incision should be carried down to, but not injure, the muscular wall of the bladder. The bladder is next separated from the uterus by a finger covered with gauze and the peritoneum perforated, either by thrusting a finger through it or by snipping with the scissors. This opening should be stretched sufficiently to permit the delivery of the uterus through it. The firm attachment of the uterus to the bladder along its median line makes it safer in many cases to liberate the sides first. The anterior vaginal wall is now separated from the bladder by blunt dissection, first on one side of the median incision and then on the other. This dissection is facilitated by grasping the edge of the incision with a long-handled forceps and pushing off the bladder by gauze pressure. These vaginal flaps should be sufficiently large to cover the uterus after it is brought into the vagina. The uterus is now delivered into the vagina and covered with the flaps. Two or three stitches at intervals of an inch or more, passed through the edges of the flaps and underlying uterus, secure the latter in place. The uterus should not be drawn down so far as to interfere with urination by pressure on the urethra, though it should be sufficiently low to give support to the cystocele. A continuous catgut suture along the line of incision completes the operation. The after-treatment is such as is usual for vaginal operations."—(Gilliam's *Text-Book of Practical Gynecology*.)

6. **Cancer of the ovaries** "Ascites is one of the first symptoms to attract attention. This is especially true of the cauliflower variety, where it declares early and becomes pronounced. Edema of the feet and ankles from pressure on the large vessels is also an early and suggestive symptom. The progressive loss of flesh and strength, the rapidity of the growth, the ascites and edema of the lower extremities taken together make an ensemble of symptoms that scarcely admits of misinterpretation. Pain is often wanting or of moderate intensity. Early in the papillary and later in the parenchymatous form infection of the peritoneum and adjacent organs occurs, followed by the development of cancerous nodules. Infiltration of the cellular tissue of the broad ligament often leads the growth to the depths of the pelvis. Large accumulations of ascitic fluid may obscure the diagnosis by interfering with the necessary manipulation. In such, the fluid may be drawn off by the trocar, or preferably, through a small abdominal incision, through which a finger may be passed into the abdominal cavity and the character, extent, and location of the growth determined."

Treatment:—"When the disease is confined to the ovary the organ should be removed, with as much of the broad ligament as is compatible with safety. It is also better to remove the opposite ovary even though it be apparently sound. Implication of the broad ligament to the slightest degree should be met by the removal of

the uterus. In case the broad ligament is infiltrated to any considerable extent, or cancerous nodules are found on the adjacent viscera or in Douglas' pouch, operative interference will be fraught with special danger and will be unavailing."—(Gilliam's *Text-Book of Practical Gynecology*.)

8. **The most common causes of sterility are:** Gonorrhea; malformation, maldevelopment or absence of any part of the genital tract; obesity; alcoholism; fistula; traumatism; dyspareunia; pelvic inflammations; lacerations; anemia; incompatibility; frequently the cause is to be found in the male.

SURGERY.

1. **The symptoms of gallstones are:** "Indefinite pains; fullness in right hypochondrium and epigastrium. *Paroxysms of colic* begin in hypochondriac and epigastric regions, spread toward navel and right scapula; generally begin in daytime, during exercise, and last a few minutes to several hours; collapse, sickness, or vomiting. *Sickness and malaise*, quite independent of colic. *Vomiting*.—At end of paroxysm; bile-stained vomit; calculus is rarely vomited. *Collapse*.—Feeble pulse; clammy skin, low temperature. *Calculi in feces*.—Absence in some cases accounted for by stone having failed to reach the intestine. *Jaundice*.—Usually occurs 12 to 36 hours after colic; skin, urine, conjunctivæ are yellow; feces are clay colored and offensive; rarely, and in old people, jaundice occurs without preceding colic; does not occur when stone is in cystic duct; is partial, i.e. feces contain bile when obstruction is partial, or when fistulous communication exists. *Temperature*.—Sometimes rigors, with temperature 103° or more, occur after colic; probably due to septic infection at seat of ulceration; fever may be of an intermittent type, associated with catarrh of bile-ducts and an impacted calculus; may be remittent, and lead on to septicemia or septic endocarditis; associated with suppuration in bile-ducts."—(Synopsis of Surgery.)

Diagnosis.—Usually follows from association of colic with jaundice, and there may be palpable gall-bladder or stone in feces.

From renal colic.—In this: Pain radiates into pelvis and thigh; vesical irritation, crystals in urine.

Lead colic.—In this: Chronic constipation, blue line, etc.

Gastric ulcer.—In this: Relation of pain to meals.

Cancer of head of pancreas—In this: Fixed tumor, loss of flesh, deep jaundice associated with enlargement of gall-bladder.

Membranous colitis.—In this: Casts and shreds of colon are passed.—(Synopsis of Surgery.)

Surgical treatment. Cholecystostomy is done through an incision parallel to and 1½ inches below the costal margin over the gall-bladder. The liver is drawn up and the intestines packed away with gauze. If the gall-bladder is distended the fluid is removed by tapping it with a trocar and cannula. The opening is then enlarged, and the stones are removed with a scoop. The bile-ducts are examined along their whole course by a finger externally, and by a long probe internally. If the interior is fairly healthy, the opening is sutured with two layers of continuous sutures and the abdomen is closed. Usually it is necessary to drain the gall-bladder for a time, in which case the margins of the opening are stitched to the peritoneum and transversalis fascia of the abdominal wound. The fistula thus established soon closes if there is no obstruction to the passage of the bile into the intestine. If not, it must be closed by a plastic operation or cholecystenterostomy.—(Aids to Surgery.)

2. **The general indications in the treatment of recent wounds are:** To stop the bleeding, combat shock, remove foreign bodies and dead tissue, make aseptic, put the edges in apposition, drain (if necessary), dress, secure rest to the part, allay undue pain, and combat inflammation.

In treating infected wounds, the first principle is to disinfect.

"Infected wounds should be opened freely to secure drainage, and hopelessly damaged tissue should be curetted or cut away. The wound should be washed with peroxide of hydrogen and then with corrosive sublimate, dusted with iodoform or orthoform, either drained with a tube or packed with iodoform gauze, and dressed with

hot antiseptic fomentations. The part must be kept at rest and internal treatment should be stimulating and supporting. If lymphangitis arises, the skin over the inflamed vessels and glands is to be painted with iodine and smeared with ichthyol, and quinine, iron, and whiskey are given internally. The temperature is watched for evidence of general infection or intoxication. The patient must be stimulated freely, nourishing food is given at frequent intervals, pain is allayed by anodynes if necessary, and sleep is secured."—(Da Costa.)

3. The breast should be thoroughly and carefully examined. Diagnosis is generally easy in advanced cases; "but in the early stages, when radical treatment is so essential, a cancerous tumor may be confused with inflammatory and other benign swellings. In *chronic inflammatory thickening* the skin may be pitted, and the tumor fixed in the breast, and ill-defined; but the whole gland is often uniformly enlarged, scars of old abscesses may be visible, and the glands are swollen at an earlier stage, and to greater size than in cancerous conditions. *Adenomata* are generally clearly limited and freely movable; there is no dimpling of the skin, and the lymphatic glands are not enlarged. *Tense cysts*, when fluctuation cannot be elicited, are similar in most of their symptoms to adenomata; and differ from 'malignant cysts' by the absence of adhesions or extension of the disease to lymphatics. *Sarcomata* are more rapid in growth and soon involve the skin, and do not affect the glands in the early stages. *Duct cancers* are apt to be multiple, are more circumscribed, and are specially distinguished from scirrhus by the bloody discharge from the nipple; they differ also from simple papilliferous cysts of the ducts by the tumor invading the breast. *Epi-thelioma* of the areola or nipple differs from eczema in its intractability to soothing treatment; and from scirrhus in its superficial and more localized situation, at all events in the early stages. In cases of *doubtful* diagnosis it is advisable to prepare for a radical extirpation of the disease; but first to incise the tumor and remove a piece from the growing edge for immediate examination."—(Buchanan's *Surgery*.)

The presence of a tumor, dimpling of the skin, retraction of the nipple, with cachexia, enlarged lymphatic glands in axilla or above or below the clavicle, and microscopical examination of an excised piece of the tumor all aid in the diagnosis of malignant growth of the breast. *Treatment* should be early and thorough. However small the tumor may be, the entire breast and its corresponding lymphatic area, as high as the apex of the axilla, should be removed; for, once infection of the lymphatic spaces has occurred, the whole lymphatic area must be looked upon as infected. Successful operations depend upon a knowledge of the *lymphatics* and *extent* of the breast. The lymphatics begin in plexuses around the acini, which converge to vessels running along with the ducts and end in a sub-areolar plexus. From this three or four main lymphatic trunks run to the axillary glands. In addition, lymphatics run along the suspensory ligaments to the skin all over the prominence of the breast from the interacinous plexuses. Also vessels leave the deep part of the breast to join lymphatic plexuses in the pectoral fascia. The plexuses in the fascia run to the axilla, and also communicate with those in the pectoralis major. Lymphatic vessels pass into the mediastinum, and also communicate with those of the opposite breast and axilla. The extent of the breast is much greater than the prominence would lead one to believe. It extends almost to the clavicle, just to the edge of the sternum, down to the seventh rib, and out to the mid-axillary line. The points, then, in operating are that the whole breast, the skin over the prominence, the pectoralis major muscle (except the clavicular portion), the fat, fascia, lymphatic vessels and glands of the axilla must be removed, and in one piece, for if cut across at any part there is danger of stranding cancer cells on the wound and so infecting it with growth. Removal or division of the pectoralis minor facilitates the cleaning of the axilla.—(*Aids to Surgery*.)

4. What is the *first thing* to be done will depend upon circumstances. Ordinarily one should not give morphine until the diagnosis is clear, as opiates are certain to mask some of the signs. On the other hand, if the pain is relieved to some extent a better examination can be made, and so there may be more certainty

in the diagnosis. The case is probably one of appendicitis.

Diagnosis of acute appendicitis: "When the three cardinal symptoms of the disease are present—that is, sudden onset of acute abdominal pain, followed by vomiting, occurring in one previously well; unilateral rigidity of the right lower abdominal wall; tenderness over the site of the appendix—the diagnosis of appendicitis is warranted in nearly every case. . . . Failures in diagnosis, however, may often be explained by the fact that the initial symptoms were insignificant, were lost sight of or were obscured by the injudicious use of opium. The commencement of an attack of acute appendicitis may very closely simulate acute indigestion, in that there occur vomiting, colicky pains, often implicating the entire abdomen, and tenderness. But in acute appendicitis there is nearly always a certain *sequence of symptoms*—pain, vomiting, tenderness—and rigidity of the rectus muscle is nearly universal. If this sequence of symptoms—(1) pain, (2) vomiting, (3) tenderness—is altered, the diagnosis of acute appendicitis may well be considered doubtful; and where acute appendicitis is present and these symptoms have not occurred in the order described, other signs are generally present which render the diagnosis certain. Fever nearly invariably appears later than the three symptoms first mentioned."—(Deaver.)

"In *acute obstruction*, as in appendicitis, the pain is first appreciated about the umbilicus; but in acute obstruction it remains in that region, does not pass to and localize itself in the right iliac fossa, and is not associated with tenderness of the right iliac fossa. In obstruction the vomiting is persistent; in appendicitis, except in the beginning, it is usually trivial and often absent, although in children it may be violent and persistent. In acute obstruction shock is much more pronounced than in appendicitis, and early and great distention of the abdomen is noted. The temperature in obstruction is usually subnormal; while in appendicitis, at least in the majority of cases, the temperature is distinctly elevated. Further, in acute intestinal obstruction the constipation is absolute, except in cases of intussusception."—(Da Costa's *Modern Surgery*.)

In *intestinal colic*, there may be vomiting, diarrhea, and flatulency. There is no local rigidity or tenderness, and the pain is more diffuse.

Treatment of acute appendicitis: The patient should be kept in bed; no food is to be given for the first twenty-four hours; after this, fluid and jellies may be given; cooling drinks may be allowed in moderation; the pain can be relieved by hot or cold applications on the right iliac region, or morphine may be given if necessary (and only after the diagnosis has been made); an enema of olive oil or glycerine may be given to empty the bowels (if loaded).

The indications for operation vary according to the views of the surgeon. Some maintain that every case of appendicitis should be operated on as soon as the diagnosis is made. Others would operate only in case of rupture, or when suppuration occurs, or in cases which do not improve in a week or so, or in cases which are steadily getting worse. Probably all would agree in taking out every appendix that has undergone more than one mild attack.

5. *Tendon transplantation*: "Having exposed the field of operation by an incision harming the adjacent structures as little as possible, and having isolated the involved and the sound tendons, the technic of grafting may be accomplished in several ways—one of which is—*Tendon-grafting by lateral attachment*: In the case of a divided tendon, the distal end is freshened by an oblique paring. In the case of a paralyzed (undivided) tendon, it is divided obliquely. That portion of the sound tendon to which the involved tendon is to be attached is freshened upon its lateral aspect—to which the obliquely divided distal end of the injured, or paralyzed, tendon is now sutured with gut by peripheral coaptation sutures, or other form of suturing. Sometimes the paralyzed tendon is not divided, but its lateral aspect freshened, just as in the case of the sound tendon—these aspects being then brought together and sutured. Especially would this be indicated where it is possible for the structure of the paralyzed muscle eventually to regain its functioning. The wound is finally closed in the usual way, and the limb put up

upon a splint in such a position as to secure relaxation of the parts."—(Bickham's *Operative Surgery*.)

6. *An abdominal wound may be closed without drainage*, if the wound is an aseptic one, if there has been no severe hemorrhage, and if there has been no damage to any viscus. *Drainage is necessary* if there has been a severe hemorrhage, if the stomach or intestine has been ruptured and the contents have escaped into the abdominal cavity, and if there has been any damage to the liver, spleen, pancreas or kidneys; also if pus is present. Drainage is necessary in most cases of peritonitis, and may be effected by rubber or glass tubes with or without gauze wicks, or a cigarette drain.

7. *Osteomyelitis. Symptoms:* Sudden onset; pains, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia may be present. It is to be diagnosed from (1) *Rheumatism*, in which more than one joint is affected and the tenderness is in the joint, and not near it. (2) *Tubercular arthritis*, in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) *Cellulitis* in which the bone and periosteum are not affected, and in which there is always a wound.

The treatment consists in relieving constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. If this fails, amputation may be necessary.

8. *Pott's disease of spine:* "There are three typical signs—pain, rigidity, and deformity; and there may be abscess and paraplegia. Rigidity is the most important of these signs. 1. *Pain*.—In the early stages it may be only of an aching character. Local pain is that felt in the situation of the diseased bones, and tenderness may be elicited by percussion over the spinous processes. Referred pain is produced by pressure on the roots of nerves in the intervertebral foramina, and is felt at their cutaneous terminations. If in the lumbar region pain may be felt in the legs; if in the dorsal region, pain may be felt in the abdomen, chest, or arms; if in the upper cervical region, pain may be felt over the upper part of the chest or back of the head. 2. *Rigidity* is invariably present. In the early stages it is due to muscular contractions to steady the painful part. In an adult it can be demonstrated by getting him to go through various movements while a hand is kept over the suspected area. The limitation of movement is better felt than seen. In a child, it is better to lay it on its face and test the flexibility by grasping the ankles, and so raising the legs and pelvis. If rigidity is present, the whole body is raised instead of the back being curved. In the later stages, when repair has taken place, the rigidity is due to bony ankylosis. Secondary curvatures restore the upright position of the body. 3. *Deformity* is due to falling forward of the upper part of the spine as the vertebral bodies become destroyed, so that cases cured in the early stages present none. Where only two are involved the deformity is angular; where a large number are affected the deformity is a curvature. When the curvature is in the dorsal region, the sternum becomes convex anteriorly, and the intercostal spaces are diminished or obliterated."—(*Aids to Surgery*.)

The diagnosis of spinal caries is easy when the characteristic deformity is well marked; but in the early stages the most reliable sign is rigidity. Tumors of the spine and aneurismal erosions may simulate caries; but as a rule other signs are present, and the symptoms steadily progress in spite of treatment.

Treatment consists chiefly in immobilizing the spine and taking the weight of the body from above the seat of disease by some form of support.

EYE.

1. *Diseases, the diagnosis of which may be aided by the findings of the retina:* Errors of refraction, retinal hemorrhage, optic neuritis, optic atrophy, embolism or thrombosis of the central artery, tubercles of the choroid, cerebral lesions, syphilis, tuberculosis, locomotor ataxia, arteriosclerosis.

Trachoma is an inflammatory condition of the conjunctiva, accompanied by hypertrophy, granule formation, and subsequent cicatricial changes.

Glaucoma is a diseased condition of the eye, produced by increased intraocular pressure, and resulting in excavation and atrophy of the optic disc, and blindness.

2. The cornea is nourished by lymph.

The function of the cornea is to render the entering rays of light slightly more convergent.

To remove a piece of steel from the cornea: "Small sharp objects often become firmly fixed in the cornea, and if not readily seen by daylight should be searched for with the aid of a lens or binocular magnifiers and artificial illumination. Apply a 2 per cent. solution of cocaine until the conjunctiva is insensitive, and then, standing behind the patient, remove the foreign body with a small spud, or if firmly embedded, with a mounted needle. If a piece of steel or iron has been fixed for some time, a ring of rust will remain after it has been extracted; this need not be removed. Bandage the eye for twenty-four hours, and if the irritation is severe use atropine and hot fomentations. The removal is rendered easier by gently fixing the globe with the left index-finger, pressing through the lower lid.

"A foreign body, especially a chip of iron or steel, is sometimes driven almost through the cornea, so that one end projects into the anterior chamber; it is then impossible to remove it by the ordinary way, and a broad needle must be entered toward the margin of the cornea, and its end used to press up the foreign body, while the wound is enlarged and the foreign body extracted; this operation requires much care, and it is best to give an anesthetic before it is attempted. The foreign body may be driven right through the cornea, so as to rest in the anterior chamber, or to be fixed in the iris or lens; to remove it make a small corneal section, and seize the fragment with fine iris-forceps. If the foreign body be iron, it may be removed by the fine point of an electro-magnet introduced through a corneal wound, or with the help of Haab's giant magnet. Some of the modern hard steels are non-magnetic; inquiry should be made as to the source of the fragment. If the lens capsule has been wounded cataract will certainly follow. If the foreign body be fixed in the iris, a small piece of the latter may be excised, bringing with it the fragment.

"When a piece of iron or steel remains embedded in the eye it becomes firmly encased in fibrous tissue. Chemical action set up by the presence of the metal causes changes in the eye, vitreous degeneration and opacities, gross pigmentation of the choroid, and optic atrophy. If iritis should supervene or the eye be blind, it should be excised without delay for fear of sympathetic disease."—(*Aids to Ophthalmology*.)

3. "The iris is a colored membrane, circular in form, hanging behind the cornea immediately in front of the lens, and perforated in its center by an aperture of variable size, the pupil; it serves to regulate the amount of light admitted to the interior of the eye, and cuts off the marginal rays which would interfere with the sharpness of the retinal image. Its peripheral border springs from the head of the ciliary body and the ligamentum pectinatum. Its free inner edge, the boundary of the pupil, lies upon the anterior capsule of the lens when the pupil is contracted or moderately dilated; with maximum dilatation of the pupil it hangs free in the anterior chamber. The iris separates the anterior from the posterior chamber of the eyeball. Its anterior surface presents great variation in color in different eyes, and is marked by radially directed, wavy lines, converging toward the circle of irregular elevations and small depressions (crypts) situated near the pupil; other finer lines are seen extending from this ring to the pupil. This appearance is produced by the subiacent blood-vessels."—(*May's Diseases of the Eye*.)

The functions of the iris are: (1) To regulate the amount of light which reaches the retina (in intense light the pupil becomes smaller); (2) to lessen spherical aberration by cutting off peripheral rays of light.

The fundus of the eye is the posterior part of the interior of the eye as seen through an ophthalmoscope.

The macula of the eye is the yellow spot of the retina and is the spot of clearest vision. It is on the inner surface of the retina. It is situated a little to the temporal side of the entrance of the optic nerve.

4. **OPHTHALMIA NEONATORUM.** *Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloth, instruments, etc.

Symptoms: Swollen eyelids, with copious purulent discharge.

Sequelæ of improper treatment: Ulceration of the cornea may ensue, and this may be followed by blindness.

EAR.

1. *Symptoms of acute otitis media:* Pain and deafness in the affected ear, slight fever, prostration, slight tinnitus.

The pain may be referred to the teeth, because ear and teeth are both supplied by branches of the same nerve (fifth cranial).

2. The particular quadrant which should be incised depends upon the condition calling for the operation. The incision should be made sufficiently long; a mere puncture is not sufficient. If possible the incision should be so placed that the opening will extend from near the floor of the canal upward and through the bulging portion of the membrane. The surgeon should avoid touching the auditory ossicles.

3. The danger in mastoidotomy is: Infection of or entry into lateral sinus or cranial cavity.

4. In impacted cerumen, there is generally sudden deafness without other symptoms such as vertigo or pain; there may be a feeling of fullness and discomfort, and cough.

In furunculosis there is severe and throbbing pain which is made worse by talking and by eating.

Inspection is necessary.

Books Received.

THE MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

REPORT OF THE U. S. INTERDEPARTMENTAL SOCIAL HYGIENE BOARD for the Fiscal Year Ending June 30, 1920. 272 pages. Government Printing Office, Washington.

SLEEP WALKING AND MOON WALKING. By J. SADER, M.D. 139 pages. Published by the Nervous and Mental Diseases Publishing Company, New York.

INJURIES OF THE PERIPHERAL NERVES. By HENRY S. SOUTTAR, M.D., and EDWARD W. TWining, M.D. 152 pages with illustrations. Published by William Wood & Company, New York.

MALARIA AT HOME AND ABROAD. By S. P. JAMES, M.D. 234 pages with illustrations. Published by William Wood & Company, New York.

STUDIES FROM THE ROCKEFELLER INSTITUTE OF MEDICAL RESEARCH, Reprints Volume XXXV. 616 pages with illustrations. Published by the Rockefeller Institute for Medical Research, New York.

TYPES OF MENTAL DEFECTIVES. By MARTIN W. BARR, M.D., and E. F. MALONEY, M.D. 179 pages with illustrations. Published by P. Blakiston's Son & Company, Philadelphia.

TRANSACTIONS OF THE AMERICAN OTOLOGICAL SOCIETY, Volume XV. Part 11. 199 pages with illustrations. Published by the Society Mercury Publishing Company, New Bedford.

SURGICAL PATHOLOGY AND MORBID ANATOMY. By Sir ANTHONY A. BOWLEY, M.D., and Sir FREDERICK W. ANDREWS, M.D. 651 pages with 210 illustrations. Published by P. Blakiston's Son & Co., Philadelphia.

NOUVEAU TRAITE DE MEDICINE. Edited by G. H. ROGER, F. WIDAL, P. J. TEISSIER, and MARCEL GARNIER. Vol. I, Infectious Diseases. 482 pages with illustrations. Published by Masson et Cie., Paris.

NITROUS OXIDE-OXYGEN ANALGESIA AND ANÆSTHESIA IN NORMAL LABOR AND OPERATIVE OBSTETRICS. F. H. McMECHAN, M. D., Editor. 97 pages. Published by the National Anesthesia Research Society.

Therapeutic Hints.

Carbolic Acid in Influenza.—C. B. Richardson, if called to see an adult having temperature, headache, pains, etc., gives phenacetin, grs. 3-5, every four hours for a day or two. Then the following carbolic acid mixture is given every four hours if cough and lung symptoms predominate, every three hours for milder and suspicious cases:

R Glycerini acidi carbolici.....ꝑꝑ lxxx
Glycerini 5iij
Syr. papaveris 5iij
Aq. ad 5viii

Sig. q. q. iv. h. vel ter in die.

He has never observed carboloria or unpleasant symptoms, and patients do not mind the taste, which is to an extent covered by syr. papaveris. The mixture rapidly relieves the cough, cleans the tongue, and tends to abort lung complications, if the case is seen early.—*The Practitioner.*

Toothache.—David I. Macht calls attention to the use of benzyl alcohol for toothache. Benzyl alcohol either alone (100 per cent.), or, still better, when mixed with an equal part by volume of chloroform, furnishes a most efficient anodyne for toothache, when introduced on a pledget of cotton into a tooth cavity, or applied to an exposed nerve. The relief thus obtained is almost instantaneous, marked, and long-lasting. He knows of no other drug, with the exception of cocaine, which is more efficient in relieving toothache. As benzyl alcohol is the least toxic of all the well-known local anesthetics, the repeated and free use of such a combination as described is free from the objections which are raised by the employment of cocaine, and it can be administered with impunity even to small children.—*Journal of the American Medical Association.*

Epilepsy.—John McCartney, from his experience in the treatment of epilepsy in an asylum, recommends a mixture containing potassium bromide and sodium bichlorate. The benefit of this treatment was very marked in all the wards; in two, where it had been in use for four months, the fits were reduced by 64 per cent., and in two other wards in which the treatment was commenced about six weeks before this report there was a reduction of 68 per cent. This method has been tried in forty-two cases. In all there was marked improvement in the mental state of the patients, and in all except one the number of fits was reduced. It was also noted that there was a great reduction in the amount of sedatives used and a marked diminution in the number of accidents which occurred.—*British Medical Journal.*

Ether Injections in Whooping-Cough.—In certain quarters in France the treatment of choice for whooping-cough is by intramuscular injections of ether. Weil and Dupur, who introduced the method in 1914, claim excellent results, while Variot and Audrain have noticed remarkable cures and complete failures. Audrain explains the failures on the basis of faulty diagnosis, holding that acute congestion affecting adenoid conditions of the nasopharynx may give rise to symptoms resembling those of whooping-cough. Up to the age of eight months a dose of 1 c.c. is sufficient; in other children 2 c.c. are injected. The injections are made every second day. Bronchopneumonic complications appear to be benefited thereby.—*The Medical Press and Circular.*

AMNESIA—THE SUBCONSCIOUS WAREHOUSE.

By J. ALLEN GILBERT, Ph.D., M.D.,

PORTLAND, ORE.

THE following history teaches so many lessons and illustrates so beautifully many of the characteristics of the subconscious that it is deemed advisable to give it permanent record. The name in the record has been modified somewhat so as to conceal identity and yet so changed as not to destroy the peculiar coincidences which occurred during treatment.

Mrs. B. came to me Oct. 8, 1920, referred by Dr. James F. Bell. She had arrived at Portland at

11 A. M. about one month previous, with her past an absolute blank. Feeling hungry, she went to a nearby restaurant, ate breakfast, and from there went to a hotel to think things over and get her bearings.

So far as conscious memory was concerned, there was nothing—not even her name. The morning newspaper lay open before her in the restaurant. Realizing that she did not have much money, she took the telephone number of an advertisement for an attendant in a hospital. She went to see the place and found, to her disappointment, that it was a hospital for the Alaska insane. When she went to register her name in the hotel, she started to write rather automatically without any definite ideas as to what she was going to write. Automatically she wrote "Broo—" and having nothing in mind to complete a real name she hastily added "ks." When she came to my office, she insisted that her name must be something like Brooks, because that name seemed to feel all right to her.

As soon as she took up her duties at the hospital she figured out that she had better keep a diary so that, if anything further of unusual nature should happen, she would not be without knowledge of the crucial events. Consequently she wrote out important events, continuing the process at my request after she consulted me nearly a month later. These notes are so significant that they are transcribed below, preliminary to a narration of the treatment as such.

I will try and write down what I can remember since yesterday. My head aches all the time and I forget so easily. I am in Portland and do not know how I got here. I found myself on the train in a sort of a daze with little money and no place to go. I got off with the other passengers and walked along and went in some place to eat. I picked up the paper that was on the table, hoping that it would help me to remem-

ber. The name Portland seemed familiar. So I ate my breakfast and read what I could, but was unable to locate myself. I seemed to feel somehow that I was alone. I did not feel sick. In fact, after eating I felt better and with so little money wondered what I should do. I had a bundle with a brown silk dress, umbrella, and also had a big brown coat and night dress, but nothing else. I never thought of applying to the police for help until to-night and now I'm glad I didn't. I am perfectly sensible, but have forgotten even my name. I ate my breakfast and went to the nearest hotel and thought I would lie down, as it was very early. I have forgotten the name of the place, but it is near the depot. They asked me to register and as I was about to write my name I seemed to get mixed. I know it isn't what I wrote, but it will have to do until I can remember better. I bought another paper of another kind, but neither places nor names were familiar. I read the ads and saw where they wanted an attendant at a local hospital. So I went to the telephone and I called up the place. It was a hospital and I told them I would go out. I came, thinking that if I were to take sick it would be the best place for me, and I found when I reached here an insane asylum for Alaska patients. I was very nervous about staying, but as I had so little money and no place to go I said I would come back. I asked to go to the toilet and found a bond for \$100 in my stocking. I knew perfectly that it was a Liberty bond and worth money. So I went back to the hotel. I had written down the name and by asking people I found the place. I had to spend a little money for aprons and some gingham dresses and then I came back to Morningside, the hospital for Alaska insane patients. I thought at first that I would tell the doctors all about myself if I could not remember in a few days. But a woman here frightened me from doing so and I'm glad now I didn't, for she seems all right. I don't seem sick, but very nervous—sort of a trembling inside. They asked me where I was from and "east of the mountains" seemed to pop in my head, so I said that. Will write again to-morrow. Perhaps I can remember then.

Sunday Night.

I got up this morning, but was in a sort of a panic when I remembered where I was, for, strange to say, I did remember yesterday and everything that had occurred. It was hard on me here to-day because I was here alone. It was the other nurse's day off. If it had not been for the kindness of a patient, a colored woman, I don't know how I would have managed. I trembled so inside and the continual headache. However, after I had eaten my dinner I felt much better and am all right to-night except that I get so awfully hot at times. I think I shall be all right soon, for tonight a man named Barnes, an elderly man who is working here, walked around the grounds with me, and he was talking about farming and I remembered a lot of sheep and cows, but it seemed so far away.

Monday Eve.

Today I remembered Harry [her son], but not his name. He is 16 and I can almost see him. Tomorrow or next day I get an afternoon off and I am going into Portland. The name seems so familiar and I shall buy some out of town papers. I am still afraid to speak of myself to the Drs. here, although they seem very nice. If it were not an insane asylum I suppose I should feel differently. I still have severe attacks of trembling and felt today as though I was going to

be sick. However, it passed and I trust everything will be all right.

Tuesday.

Harry is in school somewhere, I am sure. I can't tell how I know, but I am sure I shall remember everything soon. If I could only trust these Drs., but I am still afraid. That awful trembling comes on so suddenly that I have to go upstairs for a little while. I can remember England. That all my people are dead. Is Charlie my husband or my brother? He is dead, I am sure. People ask me questions and I must answer them some way. They were talking about Alaska today, and I know I had a brother killed up there, and it seems as though some one else was there also that I knew. I told some one that my husband is dead. Please God, help me to remember.

Thursday Eve.

I got out of town papers—Tacoma and Seattle—but I cannot find anything in them to help me. If I was not afraid, I would tell these Drs. here.

Friday Night.

I'm sure that before very long everything will come back to me, because I keep remembering incidents, but I am horribly nervous.

Saturday Night [a week later].

I went down to Portland today, but I did not meet anyone I knew, and bought Tacoma and Seattle papers again, but I cannot find anything. Guess I shall have to wait a little. No one seems to own me, and I am sure I shall be all right. Everything seems so far in the past to me. So long ago and so much trouble.

Sunday Night.

I was talking with Dr. Luckey today and he asked me quite a lot of questions about my rings, and I told him about Harry going to school and about losing money in the lumber business—all we had. It does not seem to me as though I had a home. I can shut my eyes and see furniture all piled up in a room. I shall wait a little longer. Surely, by reading the papers some one will claim me. I don't want to ask anyone to help me, for I am afraid they might not understand. Am not demented, as these poor creatures are. I have simply forgotten. I pray God that I have no dear ones looking for me, and surely if I had I would find out some way. I have a feeling that Harry is all right, and today I remembered that my mother left him a lot of money. So, surely I shall remember the rest soon, and yet there stays with me that feeling of trouble, trouble. Business or something. I can't sleep well. I try and interest myself in these poor unfortunate people, and it is only by the grace of God that I am not in their place. I remembered today that I can play on the piano a little, and on the shelves are a lot of books I have read. When we talk of medicine I can see an old doctor I used to know and also lots of little things he told me, but it is names and places that escape me. Help me to be patient, dear Lord, and be thankful that I can help these poor creatures. I won't write anything for a few days and see if that will help. I have told them that my name is Brooks and I am sure that it is something like that. I may give this to the doctors here after I know them better. If it were not for that feeling of fear that is ever present and that I cannot define. I realize that a hospital for insane patients is the last place for me, but what can I do? The work here is nothing—only to be careful—and should I be unable to remember more about myself I am probably more safe here. Everybody is nice and kind and the food is good, and I am sure I shall be all right soon.

October 7.

I have made up my mind to consult a doctor tomorrow. There is no use trying any longer to fight this battle alone. I am so upset tonight. We had such a horrible day. There is a poor Indian woman here who has been doing my laundry. She asked me today to pray for her, and I told her I would if she would pray for me. Poor Jessie and poor me. I wonder which the Lord pities most.

Friday, Oct. 8.

Today I consulted Dr. J. Allen Gilbert, a specialist on nervous cases, and he was most encouraging. I

am to write every day what I can remember and also what I dream. I have read over again what I had previously written and find a number of incidents which I neglected to tell him, or to be frank with myself, which I had forgotten until I read them tonight. So I must write every time I think of something. Just now the lady knocked on my door and handed me a check for \$16, the amount I earned last month. This is the first check I have seen for some time, and I have written hundreds of them. The Portland Telegram is advertising for a Mrs. Vina Dial. Why does not some one call for me? No more tonight.

Saturday Morning.

My dreams last night were of grain fields and a large quantity of grain in sacks and making out of checks for a lot of men and such an overwhelming desire to get away from it all. So much worry over something. This morning one of the men who works here asked me if his little cat did not resemble a coyote, and I remembered preparing meat with strychnine to poison them. I have read the morning paper, but with the usual results except that I felt disappointed when I read an item that the price of wool was lower. I find myself unconsciously looking up the price of butter fat, hay, grain and feed. I feel so much better this morning since confiding in Dr. Gilbert yesterday. He was so very nice to me Saturday afternoon. Some one asked me the name of the flower growing in the yard, and I answered immediately, "Rhododendron, the Washington State flower."

Tuesday.

Yesterday was blank as far as my remembrance of my past life is concerned. It is very depressing when it rains and I feel most awfully lonely.

Wednesday.

I dreamed almost all night of large fields and lots of sheep. There seemed to be quite a little snow, and I was helping to feed them and constantly such a desire to get away from it all. So much trouble and unhappiness. Some one asked me today if my husband was dead, and I said yes, and that I preferred not to talk about it. As time passes I feel almost indifferent. I find much difficulty in expressing myself. There seems so much to write, and yet when I try there is nothing to say after all.

Later, a gentleman said to me just a few minutes ago, "What part of Washington did you come from?" and I said, "Who told you I came from Washington?" "Why, you did. You said when you first came here that you were from east of the mountains." I felt myself blushing, and to hide my embarrassment I laughed and told him that was quite definite enough and that he could guess the place. I am going to Portland this afternoon and will take this to Dr. Gilbert in the Selling Building. I find myself looking with repugnance at the name on my check. I haven't cashed it yet. It seems almost impossible for me to indorse it. I look at it and study it, trying in vain to picture the name as it should be. I wonder if I should be more satisfied if I did know. I'm afraid my people, if I have any, will never understand such a peculiar illness. It certainly does not seem possible. "Aspasia," loss of memory. [She means "amnesia."] I know I have never heard of that before, anyway. I have a boy. But my husband, if I have one, what will he think? It will be suspicion the rest of my life. A feeling of being watched. I shall never be allowed to leave home alone, and what will that mean to me? I shall wish myself dead.

Thursday.

It is just 3 o'clock in the morning and I was awakened by the barking of two dogs. I got up and going to the window to locate the sound, found to my astonishment that the windows were in the wrong place. For a few moments I was in another room other than the one I now occupy. It was a large room with open windows at the side of the bed, the left side. The bed is a double one, with a table at the head on the right. I have been accustomed to sleeping alone in a large wooden bed. It was only a moment before I knew where I was and turned on the light. But I could still see that other room and the dogs were still barking. I am writing now so that when daylight comes I shall not forget.

Thursday a.m.

I went back to my little iron bed and fell asleep at once, but remembered everything when I awoke at six o'clock. (Religion—ask Dr. Gilbert.) [This was evidently a note to ask me what my religion was, which he did at her next call. She has a deep-seated aversion to the Catholics.]

Friday.

Every time I open my purse I miss my bank book. It is black with gold letters, and I think the checks are ink.

Saturday Morning.

I was busy all night long, it seems to me, figuring up accounts. I was sitting at a desk with a lot of checks and statements, tax receipts, and bills of all kinds. A door at my left flew open, scattering all the checks on the floor, and as I picked them up they seemed to be drawn on two different banks, some pink ones and the rest white. I was very tired this morning when I first rose and my head was aching again. The first time this week, also the same feeling of depression. I don't know much how things go and wouldn't try so hard to remember if it were not for the thoughts of my boy. I know I must have loved him, and yet I feel very indifferent about it all. The life I am now living seems to occupy my thoughts and takes up all my time. It is only at night as I lie in bed that I have such a lost, regretful feeling, and I can hear the wind blow through great, big trees; one can hardly tell whether it is wind or rain. I came across a Sunday school lesson, the simple story of Joseph and his coat of many colors. I closed my eyes and the picture of a number of small children to whom I was talking came to me. Also an old-fashioned organ on which I played. But I am sure that it is all a memory of long ago when life was as simple a story to me instead of what it has turned out to be, for when I look forward into the future and try to picture the past everything spells ruin either way. My people and friends, to say the least, will always think of me as queer and I might as well face the facts now as later and make up my mind what to do. If I find them it will mean life-long sorrow and an eternal fear of the same thing happening again, or perhaps something worse. I am going to be unhappy anyway. So perhaps it will be best that they remain in ignorance and, if I ever do remember who I am, to keep silent and go away where there is small chance of anyone finding me. I have no feeling of love for anybody and yet I am utterly desolate and homesick for something.

Friday, Oct. 20, 1920.

I had the same experience last night that occurred five nights ago. I was awakened at 3 A. M. by a voice calling "Mamma, Mamma, Mamma," and I jumped out of bed and ran to where the window should be (and in the bedroom previously described). I bumped into the dresser and immediately recognized my present surroundings. The voice was that of a man, I am positive. I went to Portland on Wednesday, as usual, and great, big letters saw "Portland Wool Warehouse Co." We shipped wool to them, and I had to wait a long time for the money owing to the war. Government inspection, I think. I don't seem to be interested in picture shows, but was having a little dental work one Wednesday and had to do something to put in the time and so I went to the Hip. In a picture shown there was a girl named Peggy, and that is the name my husband called me. But it is not my real name. I read in the papers of the disappearance of the Mayor of Vancouver and saw later that friends and police feared a lapse of memory. So possibly there are others afflicted besides myself. There is some kind of a memory connected with the Agricultural College at Corvallis, Ore., and I cannot grasp it. I have tried and failed.

Sunday Evening, Oct. 24, 1920.

I have not had any more dreams—only waking ones. His morning I went to Sunday school. Baptist. It is the nearest church, but I did not care for it. So after Sunday school was over I walked about half a mile to the Methodist Episcopal Church. I knew all the hymns and the church was much like the one I have been attending, only smaller, but the same arrangement. I did not care particularly for the pastor. In the afternoon I accompanied my patient for an automobile ride

on the Columbia Highway. It was very beautiful but absolutely new to me. After dinner I walked about two miles to a little Presbyterian church. I arrived in time to attend the Young People's meeting and enjoyed it immensely. As I sat there a picture of long ago came to me of the Junior Endeavor League and my small son, about eight years old at the time, leading the meeting, singing a song called "I'll Be a Sunbeam for Jesus." And one incident stands out so plainly that I know it must all be true. The fact that he asked his father to pray at the close of the meeting, and I also remember that my husband was very much affected by it. The evening service was good and I liked the minister. I took one of the hymnals home with me and find that I can play most of them. I walked nearly eight miles today and was not at all tired.

As stated above, Mrs. B first consulted me on Oct. 8, 1920. We had four consultations in all, the last being, by all odds, the most remarkable and instructive. During the first three consultations but little could be elicited aside from flashes of memory which I felt sure related to real events in her past life, though neither she nor I could feel absolutely sure of the fact. Almost a month had elapsed since she first landed in Portland. Fear of being adjudged insane made her keep her trouble to herself.

The case being plainly one of amnesia, no thorough physical examination was made. She did not know her age, but it was estimated to be about 46. There had been three menstruations in the past month. This fact and her age made it probable that she is in the midst of the menopause. Practically all that could be got from her at the first sitting was what she had previously written down in the histories cited above.

Hypnotism was refused for two reasons:—(1) she was greatly afraid of hypnotism, and (2) She dreaded being introduced suddenly to a memory of her past life, for she had an indefinite dread and fear of it as though she had passed through some great trouble or deep sorrow.

At the time it was a decided disappointment not to be able to see whether through hypnotism full memory could be restored by direct suggestion. But, in the light of what is to follow, it is exceedingly fortunate that the case developed as it did for the future development threw so much light on the activity of the subconscious, which would have been lost had hypnotism succeeded.

Vague "hunches" made her feel that money was in some way connected with her trouble and that her past contained things to which she had no desire to return. She described it more as an uncomfortable feeling when she considered the possibility of recovering her memory. She was refined in appearance, used good language, and was far above the average in intelligence. She was interested in papers and politics and had vague memories of having a son who, she thought, was about sixteen years of age and in school somewhere. She felt positive she had not come from the South, for she had flashes of day dreams in which snow figured positively.

Having been refused the privilege of hypnotizing her, I decided to try psychoanalysis by the so-called hypnoid method. After she had relaxed perfectly with her eyes closed I started her out of her reverie and asked her what she saw or thought. She seemed greatly surprised at seeing an old Doctor. She

could not get his name nor where he lived but could recall a number of things he had said to her some time in the past. After sitting a while in an abstracted state of mind she looked up and said, "I have had typhoid fever at some time in my life. I do not know how I know it but I feel sure that I have had typhoid fever. Maybe that is what is the matter with me." Her general appearance belied that supposition. Later, when full memory was restored all details of this typhoid fever were recalled. It occurred at the age of 14.

Further attempts at psychoanalysis brought up large flocks of sheep, a man with a dog, et cetera. This man later proved to be her husband with a valuable dog they had on the place.

While the clothes she had on did not seem familiar to her she said she felt positive that she had made the hat she was wearing because it seemed so familiar to her. She felt sure that she had either a husband or a brother—she could not say which. Just a little later she broke down and cried, saying, "that man must be my husband. I see my brother in Alaska. He was killed in Alaska."

Psychoanalysis seemed to worry her and make her nervous. It increased her depression and she felt sure that her memory of her past life would bring back some awful sorrow or tragedy and she shrank from regaining her memory. These flashes of memory worried her and made her nervous and depressed. The sitting was closed with the request that she pay as much attention as possible to her dreams, some of which are recounted in her written histories cited above.

One thing became manifest at the first consultation, viz., that but little was to be got by asking her to concentrate her attention on the point in question. But if she were asked or allowed to talk on other subjects or on related subjects there would be flashes of memory, just as though the subconscious was venturing up into the conscious but was frightened back as soon as it caught your eye. During the first three consultations there was but little to be got beyond these fragmentary and momentary flashes of consciousness which were undoubtedly outcroppings of the subconscious depicting actual occurrences in the former life that had lapsed from memory.

The last consultation was exceedingly interesting and instructive and an attempt will be made to give it as nearly as possible in its real setting. It occurred on Oct. 27, 1920. She came into the office unusually depressed. I remarked the fact and she said that she did not feel well because there seemed to be such a weight hanging over her as of impending disaster or some awful sorrow or something.

Several important things had happened to her on the way over. On a previous call she had passed a window in which there was a farm tractor on exhibition. Unconsciously she glanced at it and said to herself, "That tractor looks like ours." When she came to the office she narrated the incident and drew the inference that she must belong on a farm somewhere. During the next consultation she recalled the incident and added that she could now give the name of the tractor. It came to her as she passed the window to-day. The name was "The Bull with a Pull." I made every effort to locate the agency for that particular type of tractor but failed.

Two important incidents occurred on the street car on the way into town. She was sitting absent-mindedly and suddenly said to herself with some irritation, "This is a much longer ride than I am accustomed to. Ours at home is only 20 minutes." The thing surprised her and she recognized it as a possible flash of memory. When she came to the office she had it figured out that she must live about 20 minutes' ride from town wherever her home was. After the above incident in the street car she lapsed again into her absent-minded state, as is typical for the average street car passenger. The conductor was calling the streets as they went along. When he called 50th she caught herself rising automatically to leave the car and then inhibited the act after coming to herself and realizing where she was. From this she drew the inference that she must be accustomed to getting off at 50th street, where she lives.

A third experience during this trip was of deep interest. As she was coming along the street she noticed a sign, "Portland Wool Warehouse Co." Reflexly and automatically she said to herself, "We had to wait a long while for our money from those people," and then came to a realization of what she had said and figured out that she must have had some dealings with those people if she could only remember the facts. This flash of the subconscious was of great assistance a short time later, as will be seen.

As stated above, she was greatly depressed during this consultation. She recounted how she had gone to a picture show and one of the characters was called "Peggy." Like a flash it came to her "That is my name. That is what my husband calls me." She explained that that was not her real name but she felt sure that her real name was a very common name. It seemed to her that she ought to be able to say it right off but she could not. As is so frequently the case with subconscious data it "was on the end of her tongue" but it would not off. I said to myself, "Peggy is the nickname for Elizabeth." In this I was in error as it is Margaret instead of Elizabeth. I said, I guess your name must be Elizabeth. "No, that does not sound right to me but it is a very common name." Then I said I guess it is not worth while to try so common a name as Mary. Her eyes opened wide with astonishment and pleasure and she said, "That's my name. Mary is my name." I said, "Mary What?" "I don't know." Then she would begin to attack the problem by trying to concentrate her attention on it but this was always a failure. This instance proved no exception to that rule. I then called up the Portland Wool Warehouse people, explained the situation briefly and asked them if they could recall any female customer who had sold them wool and whose first name was Mary. They searched a while and then said they would call me later after a more thorough search. Having been successful with her before by surprising her into quick uncensored answers to questions, I turned to her abruptly and said rather forcibly and sharply, "What is the name of your bank?" In a perfectly automatic way she said, "Bank of California, National Association." and then opened her eyes in perfect surprise as if she had heard some one else answer my question and then added, "Yes, that must be my bank." This

gave another clue. I called up the local Bank of California and learned that there were four such banks, at San Francisco, Portland, Seattle and Tacoma, respectively. Here was definite help but we were still without her whole name. The pain seemed blocked.

I then suggested that in her memory she should go back to the time when she got off the train in Portland and tell me as nearly as she could all that she could remember. She started out by saying, "Well, when I got off the train from Olympia— (Here her eyes opened wide with astonishment again and she added after a pause)—Oh! I must live at Olympia." Here was another important dip into the subconscious. Always when these automatic reflex answers would come out she would look surprised as if somebody else had given the answer and then immediately begin to reason on the basis of the answer given.

We did not seem to be able to get very much more and the consultation had already lasted considerable time. She was always nervous and anxious about her imposing upon me for so much of my time when she was not able to pay me. She explained that she must have money and would probably be able to pay me. She knew she had money because she missed her check book every time she opened her purse. Furthermore, she had appealed to a jeweler regarding the value of her rings and learned that they were worth at least \$1,500 or \$1,600 at a rough estimate. At this time again she began apologizing for imposing on my time and got up to go. I had remonstrated repeatedly against her worrying about the money side of the problem and, being deeply interested in the case, I said somewhat impatiently, "Oh, pshaw, sit down and quit your worrying about my pay." In perfect surprise, her eyes opened and she said, "That's my name." I said, "What's your name," entirely ignorant of what she meant. "Shaw, Shaw is my name." After a little thought, I said, "Is that your name before you were married or since you were married?" After a little hesitancy she answered, "Before I was married." I recalled that her flashes from the subconscious had depicted checks. She had disclosed her bank and so I asked her to sit down and do some things for me just as quickly as she could. I then gave her a pad and asked her to write her name. She wrote "Mary Shaw." While she was doing this I hastily took my check book from its pigeon-hole and as soon as she had finished writing Mary Shaw I substituted my check book for the tablet with the check book open at a blank check and asked her to write her name on there as quickly as possible. What followed now was perfectly beautiful psychologically. She hastily wrote "Mary" started to write "E" and then in surprise glanced straight ahead of her and then with a quick glance at me said, "My name is Broodville." She then went back to finish the writing of the name, finished the "E" and after adding "Broodville," hesitated a little and then quickly added "Ex" and broke out crying. After a moment I asked, "What does that 'Ex' stand for?" "Executrix for the estate of Esther A. Shaw. That's my mother. She is dead." She could then see "the five graves in a row."

I then called up the Portland Wool Warehouse and told them that I had unearthed the name but

still lacked the address and asked them to look on their books for the name Broodville. They immediately answered and said they found two Broodvilles on their books. One was C. A. Broodville and the other was Mary E. Broodville. When my patient heard me speak the name C. A. Broodville as I copied the phone message, she said, "Charlie. That's my husband's name." They gave me the address and when I repeated it to Mrs. Broodville, she said, "That's our farm address. We have a house in Tacoma, too. My son is there now. The address is 5012 South I Street, Tacoma, Wash."

Now her depression increased decidedly. I wanted her to let me telegraph at once but she refused saying that she must be able to picture her husband's face first. "What would he think if he should come and I would not know him. I can see Harry's [her son's] face but I can not see my husband."

Realizing that she was not in proper surroundings where she was working, I urged her to go to my home till her husband came. I feared that memory of her past might precipitate her into further depression with possible increase of her trouble. At first she refused, but finally consented. As we entered my home little similarities between our living room and her own at home called out a description of the differences and her home surroundings began coming to her with more readiness. I startled her again with the sudden and sharp question, "How many rooms are there in your house?" Automatically, as usual, under such conditions, she said, "Sixteen," and then came again the same expression of surprise on her face and after saying, "Yes, it has sixteen," she proceeded to count up and describe the same.

Previous efforts to help her recall her husband had been unavailing. I now surprised her with, "What is the color of your husband's hair?" Automatically again came the answer, "brown," and then as though verifying the statement made by some one else she added, "Yes, it is brown." However, she was unable to recall the face of her husband plainly until he came for her the next morning. Her son and all other details came vividly, but her husband she could not picture.

Up till 11:15 P. M. data kept adding themselves rapidly with progressing ease until, on retiring, she could recall practically all her life except the trip from her home to Portland. When I surprised her and asked her quickly when was the last time she saw her husband, in the same automatic way she answered that she saw him in the door of the red barn talking to two men who had come to buy wheat. He gave a critical and disapproving glance at her high heels and she turned to go to the house. That was the last she could remember. The next morning she was able to recall the details of the trip up to the Ladies' Rest Room at the Olympia depot where she was sick and could recall getting off of the sofa a number of times to get a drink of water. The details from that time till she got off the train in Portland were still a blank. Her intended destination was a little town in Washington where they owned some property that was in need of repairs. How she came to come to Portland was still a mystery when I last saw her.

They live on a 600 acre farm. The care of the

same was recently leased to another party. It had its worries but so far as work was concerned there was nothing left for her to do but look after the wants of her husband and herself. The whole life was utterly distasteful to her, and associations other than her husband were entirely lacking. Sorrows and worries were at times overwhelming and, without going into details, there is an evident incompatibility that has left but little upon which to base the longings of a human soul. The life is a tragedy and she returns to the same conditions which have made her recent experiences possible. The husband in his ignorance came after her in anger rather than sympathy, because he had reached the conclusion that she had voluntarily left home. To add to his suspicions, a mutual friend had claimed to have seen her on the streets of Tacoma at eleven o'clock at night on a given night when she was really in Portland, as records here show indisputably and as was proven to the entire satisfaction of the husband. Notwithstanding all this, in his ignorance again he refused to take her back home because of the suspicions that would be aroused in their acquaintances by a story which, in the early part of our discussion, he was inclined to look upon as "all bunk." He had never heard of such a case and in his Scotch determination he seemed unwilling to surrender a suspicion even though all grounds were disproven even to his own satisfaction. Argument and explanation seemed of little avail and they left. Mother love is carrying her back to conditions that are trying, to say the least.

The foregoing history teems with interest from the standpoint of the activities of the subconscious. It is perfectly evident that the amnesia was only apparent rather than real. Nothing was forgotten. It had only receded to the subconscious and needed only the right association or circumstance to call the lost facts to full consciousness. That passive state of mind which is characteristic of both day and night dreams frequently released from the subconscious the "forgotten" facts that were buried there. Even while dormant in the subconscious they were not without their effect upon full conscious life. Certain experiences were accepted as having fitness or warmth in her life, while others were unreservedly rejected as new or foreign to her real self. For example, her first conscious effort after the onset of the amnesia was of this type. When requested to write her name on the hotel register, she automatically wrote the first four letters of her real name but was unable to finish it and so voluntarily added letters which would make up a substitute name. On top of it all she was able to affirm that her real name, even though she could not remember it, must be something like the one she wrote, for that name sounded good to her. The connection with the subconscious was strong but not strong enough to break through the inhibitory process which had obliterated her past experiences from full conscious life. In the same way she accepted her hat as of her own make but rejected her dress as a boughten article, though she could give no reason for her conviction regarding the fact.

At other times there would be flashes of the subconscious in full consciousness but not of sufficient clearness to be identified with self. At her entrance into the hospital where she worked as an attendant,

she was asked where she came from and "east of the mountains" seemed to pop into my head and so I said that." Subsequent to the return of full consciousness it was learned that she had made an auto trip and stayed some weeks with relatives east of the mountains, so that this was a vague conscious or subconscious impression rather than a mere fabrication.

In her diary she writes and all through treatment she keeps reiterating "—surely I shall remember the rest soon and yet there stays with me that feeling of trouble, *trouble*. Business or something." All through the early part of her treatment she was uncertain as to whether she really wanted to regain her lost memory, for she had an uncanny feeling that behind it all was some terrible sorrow or trouble and she shrank from being brought face to face with it again. One of her main reasons for rejecting hypnotism as a means of cure was a fear that the whole thing would come back to her in bulk and she preferred to approach it gradually, if she could. Books on the shelves at the hospital were familiar to her and she felt sure she had read them but could give no rational explanation for her conviction.

These vague hints or "hunches" from the subconscious were even more plainly marked in such experiences as were related relative to the ride on the street car. A monotonous ride in a street car with nothing to occupy the mind comes about as near the hypnoid state as can be got in everyday life. She came to herself and found that she had been saying to herself that this ride was longer than the one she was accustomed to at home, the one at home being only 20 minutes. She then realized that this must have been a message from former experience now forgotten. Furthermore, as the conductor called 50th street, she rose automatically to go out before coming to a full realization of the fact that she was in a Portland car instead of one at home, and she properly reasoned out that in her previous life she must have been accustomed to getting off at 50th street. On the basis of these facts she announced on reaching the office that wherever she lived she must be about 20 minutes' ride on the street car and must live in the neighborhood of 50th street, both of which proved to be true on recovery of full memory.

"Every time I open my purse, I miss my bank book." What can this be but a subconscious verification of the full conscious experience now lost in the abyss of amnesia?

On sight of the sign "Portland Wool Warehouse" she caught herself saying, "We had a hard time getting our money from those people," but had to depend on inference rather than memory for the fact that she had had dealings with them, which afterward proved to be the case. The subconscious was again caught off its guard when she automatically said to herself that the tractor was like theirs at home and then failed to connect up any conscious memory with this fragmentary message from the subconscious.

The recognition of "Peggy" and "Shaw" as her name under direct stimulation illustrates beautifully how the subconscious will yield its facts under direct forceful stimulation or association.

Furthermore, if caught unawares and then ap-

proached suddenly with a question, the subconscious would usually yield the information reflexly and automatically and the conscious would then verify the information through a process of reasoning, as though the original information had been given by some other and separate individual. As examples might be cited the way in which the subconscious yielded up the facts relative to her bank, where she last saw her husband, the color of her husband's hair, the number of rooms in her house, et cetera.

Still more interesting is the fact that her dream pictures were in terms of her past life. Dream memory had full and unobstructed access to the facts of her past life while conscious memory was shut off from the same absolutely. As examples might be cited the dreams of large flocks of sheep, the checks scattered on the floor, large fields of wheat, the barking of dogs and the calling Mamma, Mamma, Mamma, in direct association with a vivid dream picture of the room in which she formerly lived at home. These were all facts in her past life and not mere new or novel concoctions. In spite of these things assuming all the semblance of reality in her dream life, they nevertheless receded immediately into the subconscious again on the return of full consciousness.

Psychoanalysis called up many facts that proved to be real experiences in her former life.

One other thing of deep interest was very impressive during the treatment. She was continually referring to an uncanny feeling that it would be far better if she never regained memory of her past because she felt sure that in it was hidden some great sorrow or worry. This proved to be true. Furthermore, the things she least desired to recall were the things that came back to her last. One of were the things to come back to her was a rather vague but persistent impression that her son was in school somewhere. The last thing that came back to her was that about which were centered all her sorrows, worries, and anxieties.

This certainly adds endorsement to the view that we only forget the things that we want to forget. It is as though years of conscious and subconscious desire to escape her surroundings had finally crystallized into a definite autosuggested amnesia for the things which she had repeatedly wished might be forgotten never to be remembered. Even in her amnesia there was still the vague feeling that it would be better never to regain memory of the past for fear of what it contained. Consequently, the facts of the subconscious had to be literally dragged out into the light of full conscious memory. Time and again during the investigation I was impressed with the aloofness of the subconscious. It was as though it would furtively peep around the corner at you but as soon as you made any attempt to cultivate its confidence or friendliness it would scamper off again. You either had to look it squarely in the face and scare it into a spasm of revelation or else approach it in a round-about way without addressing it directly. Only glimpses of it could be gotten.

So impressive was the investigation that I seem emboldened to offer the dictum that, in this case at least, amnesia is the result of an autosuggestion, consciously or unconsciously induced, by which conscious data are crowded out of the conscious into the subconscious. It is to be classed as a self-in-

duced negative hallucination. These inhibited data lie dormant until some appropriate association or experience calls them back into proper connection with the conscious life where they belong. Just as, in a good hypnotic subject, negative hallucinations can be produced, just so can the facts of full conscious life can be obliterated from consciousness through the inhibiting effect of an autosuggestion. Coupled onto the thing that we have forgotten is some unpleasant or disagreeable association which makes us prefer to have it out of memory, and out of memory it goes. No conscious fact is ever lost outright. It can be found in the basement rummage. Furthermore, you put it there yourself.

SELLING BUILDING.

HYPERTHYROIDISM.

By M. FORD MORRIS, JR., M.D.

ATLANTA, GA.

VISITING PHYSICIAN TO THE GEORGIA BAPTIST HOSPITAL AND TO THE ANTI-TUBERCULOSIS ASSOCIATION; INSTRUCTOR IN MEDICINE IN THE SCHOOL OF MEDICINE OF EMORY UNIVERSITY.

THE subject of hyperthyroidism is too broad and far-reaching to permit a detailed discussion within the time allotted me. Therefore, we will omit much that is interesting and speculative and confine our remarks to the etiological theory of the hypersecretion, to the more important signs and symptoms and diagnostic tests, and to the best methods for the relief of this distressing condition.

First of all, it seems pertinent to inquire what is hyperthyroidism? One may define hyperthyroidism as a disease characterized by excessive catabolism of all body tissues, caused by a hypersecretion of the physiological thyroid hormone.

This disease occurs more frequently in women between the ages of 15 and 45, especially at the time of one of the sexual epochs. It is of interest to know that it occurs rarely in suckling babies, in horses, dogs and cows.

In considering the etiology and symptomatology we must keep in mind the physiology of the thyroid gland. Briefly, the thyroid secretion has to do with the regulation of metabolism, detoxication, sex-gland development, circulation, intraglandular equilibrium, and emotional equilibrium.

Now the absorption of an excessive amount of the thyroid secretion is the direct cause of the symptoms which, grouped together, we call hyperthyroidism. But the causes of the increased secretion of the thyroid hormone are exceedingly numerous. However, toxemia, either chemical or bacterial in nature, is practically always the cause. Pilocarpine, phosphorus, turpentine, and silver nitrate are notable chemical poisons. Practically all febrile infections—tuberculosis, syphilis, typhoid fever, scarlet fever, measles, pneumonia, smallpox—have been known to cause the hypersecretion. This is also true of the fetal waste matter and toxins which are thrown into the mother's blood during pregnancy. Infections of the tonsils, nasal sinuses, gall-bladder, appendix, genito-urinary tract; carious teeth, so-called blind dental abscesses and pyorrhea alveolaris, and the absorption of poison from the stomach, in cases of dropped stomach or pyloric stenosis, and

from the intestines, in cases of intestinal stasis, are the starting points of most cases.

The toxins, from whatever source, stimulate the thyroid gland to increased activity, detoxication being one of the prominent physiological functions of this gland. The continued increased secretion which occurs in the chronic infections just mentioned, causes an increased metabolic rate, resulting in the formation of the usual catabolic poison in excessive amounts. The catabolic poisons in turn serve as an additional stimulant to the thyroid gland, and so, a vicious circle becomes established.

Then there is another source of toxemia which provokes excessive thyroid activity. This variety of toxemia constitutes the psychoneural origin of hyperthyroidism. Briefly, we know that any emotional shock or stress, particularly when accompanied by trauma, produces an increased metabolism in the nerve cells. Fear, anger, deep grief, and prolonged mental strain, by subjecting the nerve cells to violent stimulation, bring about disintegration of, or excessive catabolism in, the nerve cells with the production of phosphoric acid, cholin and a particularly poisonous substance called neurin, to which the thyroid is extremely sensitive. In an attempt to detoxicate these neural poisons, the thyroid gland reacts powerfully with the result that the thyroid hormone becomes a destroyer of the nerve cells by causing excessive catabolism of the chromatin and fatty substances, particularly lecithin. In such a way a vicious circle becomes established. We see, then, that the body, in hyperthyroidism, is surcharged with three distinct varieties of poisons: (1) the primary cause of the hypersecretion, (2) the excessive amount of thyroid hormone, and (3) the various toxins resulting from the excessive catabolism of all body tissues.

The manifestations of hyperthyroidism are exceedingly numerous. The severity and number of symptoms are directly proportional to the degree of hypersecretion. The circulatory system is greatly affected. Symptoms referable to the heart are palpitation, dyspnoea, anginoid pains, and a tachycardia which persists day and night. The heart is frequently dilated, which dilatation often results in functional murmurs. Throbbing of the large blood vessels, particularly in the neck, is usually distressing. The pulse is fast and thready. A capillary pulse is often found. The blood pressure in early cases is sometimes elevated; but in advanced cases it is always subnormal in the absence of concurrent disease. Blood examination reveals a moderate degree of secondary anemia; a pronounced leucopenia, with a relative increase in the small lymphocytes. The nervous system is also markedly affected. Tremor is very prominent, which is of a fine, intention type. In severe cases the entire body sometimes trembles. The reflexes are increased. Mentally there are evidences of hysteria and neurasthenia. There are sometimes hallucinations. At times the mental picture is one of hyperactivity of the intellectual centers. At other times the patient is apathetic and depressed. Melancholia is frequent. Suicidal and homicidal tendencies sometimes occur. Thyroid intoxication is not very infrequently the cause of a type of

mental aberration similar to manicdepressive insanity. The gastrointestinal symptoms are mainly nausea and vomiting, abdominal distress and diarrhea. Examination of the gastric contents usually reveals the presence of gastrosuccorria and hyperchlorhydria. The sexual system is usually depressed, there being a decrease in desire and ability. In women, menstruation is usually very little and irregular.

The thyroid gland is usually more or less swollen and soft, comparatively smooth and compressible and frequently it is tender. A pulsative expansion is often felt or seen, and a systolic murmur is usually audible over the gland. When the intoxication is coming from an intrathoracic thyroid, or an accessory thyroid gland, the glandular symptoms are missing.

Among the signs which we notice about the eyes we may mention: (1) lagging of the upper lid when the eye follows a finger downward; (2) spasmodic contraction of the upper lid when the eye first attempts to look at a finger; (3) retraction of lids, resulting in enlarged palpebral fissures; (4) difficult eversion of upper lid; (5) infrequent winking; (6) impairment of power of convergence; (7) exophthalmos; (8) paralysis of the ocular muscles. A rhythmic systolic murmur is often heard over the eyeball, and the eyes of most of these patients have a peculiar luster and a staring or frightened expression. The skin is often flushed and 1° or 2° above normal in temperature. Excessive sweating is common. The metabolic rate is increased anywhere from 10 per cent. to 100 per cent. above normal; this increase in the metabolic rate is directly proportional to the degree of thyrotoxicosis. There is an increased oxygen intake and carbon dioxide output. Loss of weight is usually gradual and often very great. Muscular weakness is often most pitiable.

Several diagnostic tests are of much value. The metabolic rate, as determined by either of several apparatuses, is always increased, and the increased rate is directly proportional to the amount of thyroid intoxication. The hypodermic injection of 8 minims of 1:1000 solution of adrenalin causes an increase of 10-50 in both pulse and blood pressure. This increase is followed by a fall and then by a secondary rise, returning to normal in about one and a half hours. The injection of the adrenalin causes also an exaggeration of the symptoms of hyperthyroidism. The lavender area which usually develops around the site of the injection, lasts, in a case of hyperthyroidism, from one and a half to two and a quarter hours. The instillation of 8 minims of 1:1000 adrenalin solution into the eye frequently causes, in a case of hyperthyroidism, a dilatation of the pupil. It is worth while to remember that digitalis has little or no effect on the heart rate. Cases of hyperthyroidism have a low glucose tolerance. One hundred grams of glucose fed to a normal person does not produce a hyperglycemia; but this amount, even in border-line cases of hyperthyroidism, causes a marked hyperglycemia. Several complement fixation tests have been described, but being still in the experimental stage, they are not yet of value. The administration of thyroid extract is mentioned only to be condemned.

The first objects in the treatment are to discover the cause of the hypersecretion and to remove this cause. Find the chronic infections about the body and get rid of them. In the cases of psychoneural origin, diet and rest are often curable. Certain hygienic measures are valuable. Good nursing; pleasant, quiet surroundings; warm, fresh air; two sponge baths daily, with plain or salt water, and the application of an ice bag to the thyroid and cardiac regions, are all quite beneficial. Absolute mental and physical rest is a necessity in the more severe cases. Rest is beneficial to all. The administration of much water, especially the imported Vichy, is excellent. Likewise, a suitable diet is most beneficial. Due to the excessive catabolism, which occurs in these cases, a very nutritious diet is necessary to overcome this catabolic loss. This diet should consist of sweet milk, buttermilk, cream, butter, cheese, eggs, plenty of bread, vegetables, soups, stewed fruits, cereals and a simple dessert, such as custard or rice pudding. All meats should be omitted, as Falta has found that a diet rich in proteins increases the thyroid secretion, and as Rudiger, on the other hand, has found that a diet of carbohydrates tends to decrease the secretion of the thyroid. Alcohol, tea, coffee and all stimulants are harmful.

Medical measures constitute a most important part of the treatment. These measures have for their object a reduction of the thyroid secretion and an upbuilding of the body tissues. The best agents for the inhibition of thyroid activity are the vasoconstrictors, of which the neutral hydrobromide of quinine, ergotin and the salicylates are probably the best. Pituitary extract, adrenalin, scopolamine and sparteine also constrict the vessels. The bromides and veronal are helpful in relieving the nervousness and insomnia. Likewise is sumbul sedative, especially when combined with hypnol, an excellent sedative. Arsenic, in addition to its tonic effect, depresses the functions of the thyroid. Sodium or magnesium sulphate, or sodium phosphate, are excellent in maintaining intestinal function. The generous use of Vichy will, by its sodium carbonate, neutralize whatever phosphoric acid the blood may contain. Another class of remedial agents is composed of those preparations which tend to restore to the nerve cells their functional constituents which have been more or less destroyed by the thyroid hormone. Lecithin in one drachm doses, three times daily; desiccated thymus gland, which contains phosphorus-laden nucleins, in five grain doses three times daily, and sweetbreads, are the most important. In most cases, iron is of value. Several sera have been tried, some users finding them helpful, others finding them valueless.

Psycho-therapy is beneficial in all cases, and absolutely necessary in some. Often some error in the daily mental or physical life, some unknown worry, some hidden fear, or some secret sin will prove to be the root of the evil. And it is only by gaining the complete confidence of the patient that we are able to find out the inner life of the mental sufferer who is our patient, and then correct any errors or mistakes therein. We must re-

member, too, that all these patients are sick in mind as well as in body; and we must treat them accordingly.

The x-ray is a most excellent agent for depressing the excessive secretion of the thyroid. x-ray therapy is painless and easy; it leaves no scar; it causes no fatalities; when given in conjunction with proper medical treatment, its results are excellent. The results of x-ray therapy are (1) a feeling of improvement; (2) the tremor diminishes, the tachycardia subsides, and there is a gain in weight. The question of dosage is most important and is to be determined by the skilled radiologist. Knox reminds us of several precautions to be taken in giving x-ray treatment, such as a careful estimation of dosage on each occasion, small doses given frequently, adequate filtration, the use of a penetrating ray, and the use of secondary filters of leather, loofah sponge, or any material which will absorb the soft rays. The thymus should be x-rayed each time, also.

Radium, when given properly and in sufficiently large quantities, will produce equally as good results as will the x-ray. Radium may succeed where x-rays fail and vice-versa. The technique may be faultily applied in both instances. When properly employed, radium gives rise to no reaction and produces excellent therapeutic results. Neither the x-rays nor radium should produce a dermatitis.

Injections of boiling water into the thyroid gland have been done by Porter, resulting in some improvement. However, there have occurred three deaths from this procedure. Watson has used injections of quinine and urea hydrochloride with encouraging results.

The surgical treatment has been purposely considered last, as this form of therapy, in the writer's opinion, should be resorted to only after the other lines of treatment referred to have failed. Surgical treatment has been the form of therapy most often used, probably because the average physician considers the statistics in the wrong light, *e. g.*, the mortality from thyroid operations when done by Kocher and the Mayos is practically nothing—which means the deaths resulting from operation and not the cures. Judd and Pemberton of the Mayo Clinic have shown that eight years after operation not more than 45 per cent. of cases are cured. It is evident, therefore, that the mortality rate of the average surgeon is 5 per cent. or more, and that the percentage of cures will hardly reach 30. When the other forms of treatment have failed, surgery is in order. When pressure symptoms develop or malignant degeneration of the thyroid occurs, surgical intervention is necessary. It seems that the chief rôle of surgery in the future therapy of hyperthyroidism will be in removing causes of the hypersecretion.

In conclusion, I wish to emphasize the importance of making the diagnosis of hyperthyroidism before the disease has progressed to the terminal stage. At present, I am making use of the estimation of the basal metabolism, the adrenalin tests, and the glucose tolerance test chiefly in the making of an early diagnosis, and particularly in making a differential diagnosis between hyper-

thyroidism and early tuberculosis, neurasthenia, "disordered heart action," and allied disorders.

CANDLER BUILDING.

Phagedenic Vaccination.—Blanchard relates that in one of the French colonies cases of phagedenic vaccina pustules were traced to a certain supply of vaccine. Research for the supposed impurities was with negative result. It was learned that cases which did not take gave no trouble and that conversely the phagedenic cases all "took." The incubation period was normal, and the pustule developed in the habitual manner until the third or fourth day of its evolution, when a grayish exudate appeared of fetid odor. Ulceration then developed with adenopathy and fever, but no other symptoms. Bacteriological tests then showed the presence in pure culture of the bacilli and spirillum of Vincent's disease. The abundant flies of the locality were doubtless responsible for the infection, and the act of vaccination evidently prepared the soil for the latter.—*Le Caducée*.

A CONCEPT OF X-RAY PATHOLOGY.

IV. CARDIOPATHY.

By A. J. PACINI, M.D.,

WASHINGTON, D. C.

CHIEF OF LABORATORY AND X-RAY SECTION, HOSPITAL DIVISION,
 U. S. PUBLIC HEALTH SERVICE.

WHEN the heart is greatly hypertrophied there is little difficulty in recognizing the condition by the x-ray. If the hypertrophy is of only moderate extent, its x-ray recognition is increasingly difficult. In spite of the difficulty certainly to recognize a moderate hypertrophy from the x-ray silhouette of the heart, the x-ray study of this organ remains the most accurate measure for the determination of the actual size. The two methods most exploited for the accurate estimate of the size of the heart are those of orthodiagraphy and teleroentgenography. Orthodiagraphy possesses the advantage of giving a graphic outline which corresponds theoretically to the exact size of the object being contoured. It is economical in material; but it requires much time and great skill to effect an orthodiagraphic measure. Teleroentgenology is more simple, quicker and accurate; but it demands the proper allowance for the enlargement of the heart shadow resulting from the divergence of the rays in producing the silhouette. If the distance from target to plate be 2 meters, and the patient exposed always in the ventrodorsal position, the correction for ray divergence becomes fixed and therefore easy to apply.

In the chest the heart contour lies approximately one-third of the distance from the front to the back of the thorax when the measure is taken at the lower part of the sternum during expiration. It is necessary, therefore, that an allowance be made for the divergence incident to the distance separating the heart from the x-ray plate. It is experimentally determined that the silhouette area must be decreased 1 per cent for each 3 centimeters of distance from the front to back of the chest and a given diameter, 1 per cent for each 6 centimeters. As a routine for an adult of average size, 6 per cent reduction of the silhouette area or 3 per cent reduction of a given diameter, will give the exact size of the heart contour with sufficient accuracy to obviate the necessity of measuring the anteroposterior diameter of the chest. Bardeen, in discussing the conclusion incident to heart silhouettes when a shorter distance than 2 meters from the target to the plate is used says:

Allowance must be made not only for this variation in distance, but also for a variation in distance of the heart contour from the plate which enters in as the target is brought nearer to the heart. This factor also enters in at the two meter distance in ventro-dorsal pictures, the heart contour being further from the front of the chest in the dorso-ventral than in the ventro-dorsal position. For determining the average distance of the heart contour from the plate the stereoscopic method gives the best results. This is based on the distance of corresponding points in two silhouettes from a fixed line on the plate perpendicular to the line of shift of the tube. The average distance of a series of such points on the contour gives the average distance of the contour.

Knowing the distance of the target from the plate, the length of the shift of the tube and the distance of the shift of a given point in the two silhouettes it is easy to calculate the distance from the plate of the point on the heart which casts this point of shadow.

The formula is $x = \frac{A \cdot C}{A + B}$ where

x = distance of point on heart contour from the plate.
 A = distance of shift of given point in the two silhouettes.

B = distance of shift of tube.

C = distance from the target to the plate.

The formula for determining the relation of the size of the area of the silhouette to that of the area enclosed by the heart contour is as follows:

$$x = \frac{100 B^2}{A^2}$$

x = area enclosed by the heart contour.

100 = area of silhouette.

A^2 = square of the distance from the target to the plate.

B^2 = square of the distance from the target to the heart contour.

The formula for determining the relation of a given diameter of the heart silhouette to a given diameter of the heart is as follows:

$$x = \frac{100 B}{A}$$

x = length of diameter of heart contour.

100 = length of diameter of silhouette.

A = distance from the target to the plate.

B = distance from the target to the heart contour.

In the two-distances method of estimating the size of the heart two pictures are taken, one with the target a shorter distance from the plate than the other. The most convenient distances are one and two meters. When these distances are chosen the following formula may be used:

$$x = \frac{200 A - 200a}{2 A - a}$$

x = distance of plane of the heart contour from the plate.

A = square root of area of heart silhouette in picture taken at one meter.

a = square root of area of heart silhouette in picture taken at two meters.

If desired a given diameter may be used instead of the square root of the area.

$$x = \frac{A \cdot a}{2 A - a}$$

x = diameter of the heart.

A = diameter of the heart silhouette at one meter.

a = diameter of the heart silhouette at two meters.

$$x^2 = \frac{a^2 (200 - x)^2}{200^2}$$

x^2 = area enclosed by heart contour.

a^2 = area of silhouette at two meters.

$200 - x$ = distance from the target to the plane of the heart contour.

Heart-Body Ratio.—By an exact method of weighing in which he dissected the various chambers of the heart, Mueller established a table not only of the absolute weight but also of the fractional weights of the cardiac parts. In a general way, Mueller found that the weight of the entire heart increased with the body weight, the proportion between the two decreasing as the body weight increases. Grober gives Mueller's table (Table I).

Bardeen provides some tables that can be used only when the x-ray plate is made with the following technique: patient with sternum flat against upper plate holder; target-plate distance six feet; target level opposite spine of the ninth thoracic vertebra; exposure made while the patient holds breath after a moderately deep inspiration. It is well to use an intensifying screen in order to diminish exposure time. Le Wald advises giving the

TABLE I.

Body Weights in Kilograms	Absolute Weight of Heart in Grams.	Ratio of Body Weight Milligrams per Gram.
1-10	28.9	5.87
10-20	78.9	5.20
20-30	133.5	5.49
30-40	193.3	5.47
40-50	230.2	5.10
50-60	264.3	4.81
60-70	297.2	4.45
70-80	322.3	4.37
80-90	359.0	4.28
90-100	376.3	4.01
100-110	358.5	3.46

patient a glass of water to drink immediately before making the exposure and to have the patient swallow air along with the water. This expedient induces the formation of an air bubble in the stomach, which air bubble assists in outlining the apex of the heart. When this technology is used the table furnished by Bardeen (Table II) is found useful in studying cardiac silhouettes.

More recently Le Wald and Turrel in an article entitled the "Aviators' Heart—Roentgen Ray Studies under Conditions Simulating High Altitudes," give the figures for their observation on the relation existing between the weight, height, transverse diameter of the heart—measure both at inspiration and expiration. These figures are not entirely in accord with those of Bardeen. A study of the table supplied by Le Wald and Turrel would indicate that when the body weight is constant, there is no apparent relation between the increase in height and the transverse diameter. Also, when the weight and height are constant, in many instances the transverse diameter varies. The table from Le Wald and Turrel slightly modified and rearranged is reproduced. (Table III.)

THE NORMAL HEART.—In the dorsoventral position the radiopacity caused by the heart silhouette should be studied for two criteria; first, for the measurement of the various parts of the silhouette and also for the total area of the shadow; and, secondly, for the form of the right border of the silhouette and also of the left border of the cardiac contour.

In the measurement of the heart, a median line is drawn on the plate which bisects exactly the cardiovascular stripe. From this median line a tangent is drawn to the right of that part of the cardiac curve that extends farther from the central mark; and similarly, on the left side, a tangent is drawn from the central line to the point farther out on the ventricular shadow. The line on the right is designated MR, and when measured in centimeters gives the right diameter of the heart; the tangent on the left is ML and gives the left diameter of the heart. The sum of MR plus ML gives the total transverse diameter of the heart. Under normal conditions the relation between the values of MR and ML is expressed by the following proportion; MR: ML: : 1:2. Various investigators draw many other lines and make many other measurements in addition to the ones just described. One useful measure used by Hirsch is that of the angle formed by the general shape of the left ventricular contour as it meets the line ML. Normally this angle should be about 45 to 50 degrees. Obtusity of the angle points to hypertrophy incident to mitral stenosis or mitral

TABLE II.

Table showing relations of a heart shadow area of a given size to approximate transverse diameter, body weight, heart weight, heart muscle weight, heart volume in diastole, and height for either sex, at a given age. Individual at rest, sitting. (Bardeen.)

insufficiency. Without adding an additional line it has been the experience of the writer that a useful measure in connection with the diagnosis of heart lesions rests with the estimate in centimeters of the difference that separates MR and ML along the median line. This is virtually another way of measuring the ventricular angle suggested by Hirsch. It gives the same amount of information as does the ventricular angle measurement, and has the advantage that it does not necessitate marking the x-ray plate with needless and possibly confusing pencil lines.

Cardiac Curves.—On the right side, in the normal cardiac contour, two curves are distinguishable. The upper one is that produced by the superior vena cava; the lower one, by the right auricle. On the left side four curves can be distinguished, though most generally only three are present. When four are seen, these are, from above downward, the descending arch of the aorta which bulges out very pronouncedly below the clavicle; a curve just below the aortic arch, the pulmonary artery; below the curve of the pulmonary artery there can sometimes be made out a small curve due to the shadow cast by the left auricle. This last curve is sometimes missing even in normal plates. The largest and most dependent curve is that of the contour of the left ventricle.

FIG. 1.—A is the ascending aortic arch. PA is the curve cast by the shadow of the pulmonary artery. LA is the left auricular curve and may not always be visualized on the x-ray plate. LV is the shadow of the left ventricle. ML is the maximum length from the median line CC to the point farthest from this median line on the curve LV. MR is the maximum length measured as for ML, but on the right side. RA is the curve of the right auricle. SVC is the shadow cast by the superior vena cava. The diagram illustrates a normal cardiovascular orientation.

A schematic relation of these curves is shown in the accompanying diagram, Figure 1.

MANIFESTATIONS OF CARDIOPATHY.—Myocardial pathology is manifested, when of eccentric type, by

changes in the total area of the heart silhouette and by changes affecting the normal curves just described. Both of these changes can occur as a result of a valvular disease. Obviously, from x-ray pathology, a valvular disease can not be recognized until it has induced manifest anatomical changes in the size or in the configuration of the heart shadow; so that changes due to valvular lesions registering on an x-ray plate point to advanced pathology.

Aortic Stenosis.—Three clinical stages of aortic stenosis are recognized. In the first stage, aortic stenosis produces no demonstrable effect upon the mechanism of the heart. Therefore, first stage aortic stenosis is without x-ray pathology. In the second stage, the initiating of which appears to be dependent upon the peripheral resistance offered by the vessels, certain circulatory manifestations assert themselves characteristic of a progressing hypertrophy of the left ventricle owing to the increased work that is thrown on this chamber. So long as the compensation is good, and the dilatation of the left ventricle is not marked, the blood flow from the lungs is not seriously retarded; therefore, there is no evident congestion visible from the x-ray pathology in the lung areas, neither is there any obvious change in other parts of the heart.

The second stage of aortic stenosis is the first to show in x-ray pathology. In the beginning of second stage aortic stenosis the only x-ray pathology visible in an increase in ML the left transverse diameter, the increase effecting the total transverse diameter, increasing the proportion between MR and ML, and diminishing the perpendicular distance between MR and ML.

As the stenosis increases, or the ventricle weakens, the dilatation becomes greater. The blood flow through the lungs is impeded and this additional pulmonary resistance affects the mitral valve, which becomes insufficient. In advanced second stage and beginning third stage aortic stenosis, then, in addition to the changes affecting the left ventricle the x-ray signs of mitral insufficiency are superadded to the pathology.

Aortic Insufficiency.—When an insufficient valve permits the blood flow from the aorta into the left ventricle, the increased quantity that the left ventricle is thus compelled to propel at each systole induces a dilatation of the left ventricle. This hypertrophy results in an increase of the curve on the left with a corresponding increase in the ML di-

ameter and therefore proportional increase in the total transverse diameter. The curve on the right normally due to the superior vena cava is still present; but in aortic insufficiency it represents the ascending aorta which, by its prominence and superposition, masks the superior vena cava. The descending aortic curve, the pulmonary artery curve and the left auricle curve are barely changed; but the left ventricle curve is markedly enlarged. The perpendicular distance between MR and ML is decreased. The heart assumes a transverse position.

FIG. 2.—On the right side (left in the diagram) the curve above that of the right auricle is due to the shadow of the ascending aorta superimposed over that of the superior vena cava which should normally occur in this location. LV is markedly enlarged. The entire organ has assumed a more transverse position.

Mitral Stenosis.—The chambers immediately behind the auriculoventricular valves possess a weaker muscular wall than the chambers behind the semilunar valves. In mitral stenosis, the flow of blood is obstructed from the left auricle to the left ventricle. The left auricle, having a relatively weak muscular wall, becomes puffed; so that, in mitral stenosis the shadow of the small normal left auricular curve become prominent and gibbous. The heart is not otherwise enlarged. (See Figure 3.)

Mitral Insufficiency.—In mitral insufficiency, so far as the left ventricle is concerned, the effects are very similar to those produced when the ventricle is called on for increased exercise. The left ventricle, therefore, hypertrophies. The x-ray pathology manifests an increased ML and a generally larger total heart silhouette. The perpendicular distance between MR and ML is generally increased; although it may not show an increment proportional to the pathology. (See Figure 4.)

Dropped Heart.—In dropped heart the cardiac silhouette is generally smaller than usually observed. The curves are generally normally retained. The entire position of the heart is relatively low in the thoracic field. The normal ratio between MR and ML is disturbed so that MR and ML more nearly approach equality. It is assumed that dropped heart most often occurs in persons who show a predisposition to pulmonary tuberculosis. From x-ray pathology, the statement cannot be either substantiated or refuted; but in the examination of many tuberculous

FIG. 3.—Mitral stenosis. In pure mitral stenosis the x-ray pathology is evidenced by the enlargement of LA, the curve due to the hypertrophied and dilated left auricle.

pneumopathies (25,000), the x-ray evidence showed relatively fewer dropped hearts than other forms; the proportion was practically one dropped heart to eighteen others. (See Figure 5.)

Kimoroentgenography.—In the study of sinus arrhythmia kimoroentgenographic evidence is of great use. The pulsations of the various heart chambers can be studied with the x-ray through the

FIG. 4.—Mitral insufficiency. The entire cardiac shadow is enlarged. Although the pulmonary artery is prominent, the prominence is not due to an enlargement but to a displacement incident to the general hypertrophy of the heart.

method first introduced by Gocht and Rosenthal. In this method the patient stands with anterior chest wall against a lead screen in which there is a narrow horizontal aperture. The screen is movable and can be placed opposite the portion of the heart to be studied. Adjustment is made under fluoroscopy, and when the desired heart chamber is localized, an exposure is made while a photographic film or plate is moved against the slit. This method has not been used sufficiently generally to permit of any formulae to present relative to the various sinus arrhythmias and their x-ray pathology.

Pericarditis.—Pericarditis is always due to bacterial infection. Streptococci, staphylococci, pneumococci and tubercle bacilli are the most frequent organisms inciting pericardial inflammation. Acute forms of pericarditis are classified according to their exudates as fibrinous or dry, and pericarditis with effusion. Fibrinous pericarditis may be accompanied with only a slight exudate; but when the exudate increases in volume it forms villi on the epicardium, giving rise to the condition known as cor villosum. The x-ray pathology is manifested by the projection of radiopaque villus masses between the cardiac outline and the pericardial delimitation. When healed, the fibrin may be entirely absorbed; or it may undergo organization leaving sclerotic areas diffusely scattered over the heart surface.

Pericarditis With Effusion.—In this, the fibrinous exudate is accompanied by a serous, hemorrhagic, or purulent fluid. As the fluid accumulates in the pericardial sac it gravitates to the most dependent por-

FIG. 5.—Dropped heart. In this the normal curves remain, the entire heart hanging lower in the thoracic field.

tion when the patient is x-rayed in the upright position. As the volume of fluid increases, the pericardial sac distends and becomes pear-shaped. The fluid in the sac is radiopaque; so that the x-ray path-

ology of pericarditis with effusion is that of a pear-shaped shadow replacing the former normal cardiac outline. It is a distinctly recognizable entity. There is nothing that can be confused with peri-

FIG. 6.—Pericarditis with effusion. The cardiac contours are eliminated owing to the distention of the pericardial sac incident to the effusion.

carditis with effusion when the effusion is of consequential volume. The shadow is further characterized by the relatively equal distribution of the pear-shaped rotundity on each side of the mid sternal line. (See Figure 6.)

The non-inflammatory affections of the pericardium, including hydro-pericardium and hemopericardium, are not to be distinguished, from x-ray pathology, from the inflammatory pericardial effusions.

Aneurysms.—Aneurysms are chronic dilatations of arterial lumens in which the wall undergoes a new formation. They may be circumscribed or discrete. The x-ray pathology of aneurysms is elicited by dorsoventral examinations and also a right oblique position. In schematic representation the aorta can be seen in the dorsoventral position as the uppermost curve on the right of the sternum. This is the descending arch. The ascending arch seldom protrudes from the left of the sternal plate. In the oblique view, the aortic shadow is seen as a cylinder of uniform diameter just behind the sternal plate. (See 1, Figure 7.) The aorta may tumefy diffusely usually as the result of a specific aortitis, in which case the shadow to the right of the sternum pro-

FIG. 7.—Above are shown in diagram the relations between the sternal plate and the aorta when the exposure is made in dorsoventral posture. Below, by exposing obliquely, the aortic shadow is cast to the side of the sternal plate. 1, represents that portion of the aortic arch visible in a normal case; 2, represents a general dilatation or aortitis; 3, represents a fusiform aneurysm. In 4, the sacculated aneurysm is not visible because hidden by the sternal plate.

trudes with greater accentuation, and the shadow to the left of the sternum appears definitely enlarged. In the oblique position the cylinder is much wider than normally. (See 2, of Figure 7.)

In fusiform aneurysms, in which physical signs are more prominent than the symptoms, affecting particularly the ascending arch, there is seen on the x-ray a widening to the left of the sternum with

FIG. 8.—Ascending aortitis. The curve normally due to the superior vena cava is masked and replaced by a more greatly accentuated curve incident to the aortic hyperthrophy and dilatation.

little or no change on the right. In the oblique form the cylinder shadow is replaced by a club shadow, narrow at the base and widened and round above. (See 3, Figure 7.)

In the sac form aneurysm, the bulging occurs usually in the transverse arch, interior wall, between the ascending and descending portions of the aorta. This part of the aorta falls behind the sternal plate; so that no x-ray pathology can be depicted in the radiograph. In the oblique position, the bulging of the sac aneurysm does not show. (See 4, Figure 7.)

Under fluoroscopic examination a valuable sign useful in distinguishing aneurysms from other tumefactions is the pulsation present in the dilatation when due to aneurysms. If the pulsation is present, the indications are in favor of aneurysm; but the sign is not infallible, for pulsation may be noticed in some aneurysms, and a wave-like motion difficult to differentiate from pulsation may be present in tumefactions other than aneurysms involving the mid sternum.

It is difficult to differentiate between aneurysm of the ascending aorta and dilatation of the ascending aorta incident to specific aortitis. From the x-ray pathology there is a widened aortic arch above the base of the heart, which widening is less marked in aortitis than in aneurysm of the ascending aorta. The two may in many cases be confused, and clinical methods other than x-ray must be resorted to for the final differentiation. Specific aortitis shows on the x-ray plate in the manner indicated in Figure 8.

FIG. 9.—Aneurysm of the ascending aorta. As in Fig. 8, aneurysm of the ascending aorta produces a bulging of the ascending aortic curve superimposed on the curve due to the superior vena cava.

Aneurysm of the ascending aorta is typified on the x-ray plate by a more accentuated cylinder as illustrated in Figure 9.

Arteriosclerosis.—Calcific infiltration of the ar-

teries may sometimes be noticed in special regions, as in the popliteal space or over the os calcis. The x-ray evidence is distinct and can not be mistaken for much else. In general, the x-ray fails to indicate calcific infiltration of the arteries unless this infiltration is markedly pronounced. Immediately following a salvarsan injection into the median basilic vein, an x-ray exposure of the arm will sometimes show the course of that vein. There is no great x-ray benefit to be derived from the ability to outline the vein in this manner; but the fact that it can be visualized through the use of an injection might be remembered with the view to usefulness should an occasion arise.

THE DIET AS A POSTOPERATIVE FACTOR IN GASTROINTESTINAL DISORDERS.

By LOUIS HENRY LEVY, Ph.B., M.S., M.D.,

NEW HAVEN, CONN.

FROM my experience as a gastroenterologist, there has been forced upon me the conclusion that the postoperative treatment, from the dietetic standpoint, of duodenal ulcer, ulcer of the stomach, and gastric conditions caused by extragastric lesions is neglected either because of a poor knowledge of the subject or through thoughtlessness. Statistics have shown repeatedly that the gastric or duodenal condition is not always cured by operative procedures. As a matter of fact the more conservative and more experienced gastroenterologists are absolutely averse to surgical procedure in duodenal and gastric conditions unless there is some immediate danger. On the other hand they prefer medical treatment by the proper and accepted methods for a period even as long as one year or a year and a half when necessary. For it must always be borne in mind that even though, to all intents and purposes, surgery offers much quicker relief, nevertheless, the complications arising during the operation and post-operatively make one hesitate before advising operation.

It is in those cases where there is no question about the necessity of operation, that it is absolutely essential to consider the postoperative care of the patient as well as the surgical procedure itself. For the successful outcome of an operative case, it is very well known that the treatment following operation is as important as the operation itself. To carry this point a step further, it is also of importance that the care of the patient should continue for an extended period after the time that he is discharged by the surgeon as cured. Often the duration of such a treatment will be as long as several months or even a year. There is no absolute means of judging this period. It depends on the symptoms. As a matter of fact there are cases which have experienced considerable relief and even absolute freedom from symptoms for a month or more after operation. The symptoms will recur even after this period of relief when there has been carelessness in the diet. As a matter of fact many of these patients, experiencing for the first time in years such marked relief from their symptoms, are very prone to abuse their privileges with the result that the same conditions that caused their former lesions recur and tend to create a pathologi-

cal state similar to that present before the operation.

In the dietetic treatment following operation for duodenal ulcer, gastric ulcer, and extragastric conditions producing gastric symptoms, there must be considered the pathological condition of the stomach and duodenum. The common conditions are duodenal ulcer, gastric ulcer, and various degrees of gastritis resulting indirectly from appendical or gall-bladder disease. Aside from the injury present in the form of the ulcer, there is added, following the operations, trauma resulting from the operation itself. This trauma results whether there has been performed a resection of the ulcer, a gastroenterostomy, or even a pyloric resection. The existent gastritis produced by extragastric conditions is further aggravated by the action of the ether, either swallowed directly or excreted through the stomach. These in brief present the pathological conditions which must be borne in mind and which must be dealt with postoperatively.

The diet following operations is dependent as a rule upon the institution in which the operation is performed, and also upon the customary method of the surgeon himself. Institutions differ as to the prescribed diets, usually arranging the diet to fit their economic state. From a financial standpoint it is no more expensive to prepare for the patient the proper kind of food than it is to dole out a diet not suited to his particular case. On the other hand another factor, such as insufficient help to prepare the food properly, adds another and more difficult problem. For the first few days the dietetic treatment differs very little whether the operation has been performed on the duodenum, stomach or outside of these organs. The rule is usually to avoid anything which may tend to evoke any irritation producing conditions injurious to the healing of the wound. The patients are given fluids at first in very small amounts and this is gradually increased if there are no untoward symptoms. In the extragastric conditions this is soon followed by a soft diet for a few days, then a semi-solid diet, and later, towards the end of the convalescence and just preceding the discharge of the patient, a more solid diet. After operations on the duodenum or stomach, there is usually a longer interval before the semisolid diet stage is reached. This, too, is dependent to a great extent on the improvement of the patient and the custom of the surgeon.

The expressions applied to the diets such as, fluid, soft, semisolid, and solid are very often too loosely used. It is common practice for the surgeon to order offhandedly a liquid diet or any of the other diets without stopping to consider of what these diets may consist. For example, I have in mind a patient whose condition, a gastric ulcer, was such that only a resection of the ulcer and not a gastroenterostomy was permissible. Within a week after the operation, the patient, having been placed on fluids was given coffee, an article of food which he had not used for years and which had always brought on symptoms. Being assured that coffee would produce no ill results he consumed it with no apprehension. Following his discharge as cured, the symptoms, present before operation, soon re-occurred and were just as bad as before. Similar examples might be mentioned of improper diets given

to patients under the guise of soft or semisolid diets.

In the dietetic treatment of all these cases, the measures employed for a varying period following the operation should be the same as during the medical treatment of the condition. Although it is advisable for the surgeon for his private cases to have a more thorough knowledge of the action of foods, especially their chemical and physiological action, it is much better for him to work in co-operation with a gastroenterologist proficient in dietetic treatment. This should especially be done in the case of ward patients in public institutions. Each patient becomes a case unto himself and should be treated accordingly. He should be watched as to, symptoms, and the diet arranged in accordance with the symptoms. When he is discharged as cured by the surgeon, he should be turned over to the care of a specialist in dietetics for a varying period for further observation and treatment.

All foods possessing any stimulating or irritating action should be avoided. All tendencies toward hypermotility and hypersecretion, especially hyperacidity, should be combated. In other words the stomach and duodenum, as any other part of the body where a pathological lesion exists requiring rest, should be given as much rest as possible. Rest of the part is the greatest asset towards the healing of the injury. And by rest is meant physiological rest as well as dynamic rest. Stimulating foods are to a certain extent irritating. These foods tend to stimulate or irritate by a mechanical or physiological action. The mechanically irritating foods are the coarse fruits and vegetables containing indigestible constituents. It has been found that these foods, even when given in a finely divided state, are irritating, hence, they should be eliminated entirely from the solid food list. The physiological irritants are those that act directly on the musoca producing physiological changes, such as, an increased congestion. For with this increased congestion there follow hyperacidity and hypermotility.

Spicy foods with pepper or mustard and other condiments all tend to have this effect. Other physiological irritants are those that act on the secretory cells indirectly and produce an increase in the acid content. Coffee, tea, meat extracts, and certain meats themselves have this tendency. Foods of another class which act differently and cannot be classified as either stimulants or irritants are the fats or fatty foods. These prevent proper rest to the stomach by unduly prolonging the emptying time of the organ.

With a general knowledge of foods that should be prohibited it is a simple enough matter to make out a diet list of foods that are suitable and proper. For the convenience of those who have occasion to treat these cases postoperatively, I am appending a list of foods arranged in the order of their consistency. These foods have been selected with the one idea uppermost in mind, namely, that none shall be stimulating or irritating to the stomach.

Fluids: Water, whey, strained gruels, lemonade, orangeade, orange juice, plain or malted milk, chicken broth, creamed soups without vegetables.

Soft Diet: All foods in the liquid diet, eggs boiled at least 3 minutes, bread, potatoes (baked, boiled or mashed), peas, milk toast, boiled cereals.

except oatmeal, such as rice, farina, cream of wheat, hominy, wheatina; puddings, such as bread, rice, tapioca, corn starch, sago containing no raisins; custard, ice cream, gelatin preparations, strained jellies, broths containing noodles or rice.

Semisolids: Foods in the above list, chicken, broiled fish, except salmon and mackerel, cream or pot cheese, macaroni.

It has been my practice in those of my cases operated upon privately to cooperate with the surgeon in the after care. As a result of this cooperation, there have been very few recurrences of symptoms in these cases and this success has prompted the writing of this paper. I have been convinced from this that by properly following out the above suggestions and recommendations, there is every reason to believe that there will be a reduction in the number of failures following operation in the class of cases mentioned in this paper. As a result of this, greater confidence will be placed in surgical interference for the cure of duodenal and gastric ulcer and for the relief of gastric symptoms in extragastric disease.

1172 CHAPEL STREET.

THE ACRIFLAVINE IRRIGATION TREATMENT OF GONORRHEA.

By LEWIS T. MANN, M.D.,

NEW YORK.

ASSISTANT UROLOGIST, MT. SINAI HOSPITAL DISPENSARY.

As the use of acriflavine in the cure of gonorrhea and its complications is becoming more common since the original utilization by Davis and Harrel¹ and by Watson² during the World War, it is of interest that the results of such treatment be reported.

It is needless to go into the history of the discovery of acriflavine, its nature, properties, etc.; but it is of importance to consider the advantages of using this dyestuff and the technique employed. Acriflavine is highly gonococcicidal³, inhibiting a growth in cultures in a dilution of 1:300,000, being 600 times as strong as protargol.

The penetrating powers are very great,⁴ as experimental studies show, for after injection into the urethra it is found to penetrate to the muscular layers, making it especially useful when the gonococci have gone deeply into the urethral tissue.

The solution suitable for irrigation, a 1:4,000 strength, is absolutely bland and non-irritating to the urethra and bladder, there being no burning or dysuria following daily use over a period of a few months in complicated cases. When the urethra is considerably inflamed the meatus swollen, and dysuria present, acriflavine may be used immediately without pain or discomfort to the patient.

The technique employed is that of Watson, a 1:4,000 solution of acriflavine in physiological saline, body warm in temperature, being used once daily.

For the sake of convenience and to obviate the necessity of either keeping a great bulk of solution on hand or of making up a solution from the powder each time, a stock solution of a 1:500

acriflavine containing a dram of sodium chloride to each two ounces, is kept on hand. A more concentrated solution will "salt out" and form a precipitate of the dye.

In preparing an irrigation, two ounces of this stock solution is diluted up to one pint with warm water, yielding a 1:4,000 solution of acriflavine in a physiological saline solution.

The treatment of an acute anterior involvement consists of a daily irrigation of the anterior urethra, with one pint of solution prepared according to directions stated; and of retaining the solution in the anterior urethra for ten minutes at the end of the irrigation. Even in cases where there is considerable inflammation with a painful swollen canal and meatus, acriflavine may be used immediately, as it is absolutely non-irritating and because of its marked penetrability will bring the condition under control within a short time. But for the drinking of ten to twelve glasses of water daily, this constitutes the entire treatment, the patient using no hand injections.

If during such treatment the second urine becomes cloudy, indicating posterior involvement or in primary acute anteroposterior urethritis, intravesical lavage is used immediately, providing the symptoms are not hyperacute. In that case, anterior irrigations alone are used until the severity of the symptoms lessen, when intravesical irrigation is instituted.

When a subacute or chronic posterior urethritis plus prostatitis exists, providing there be no acute epididymitis, daily intravesical irrigations may be used immediately and the prostate massaged on the injected bladder bi- or tri-weekly.

The efficacy of the treatment of gonorrhea with acriflavine must be judged by the results.

Watson, who treated 222 cases in the British Army, with no other remedy than flavine, states that in 198 cases, those uncomplicated, the average time for cure was 15.4 days. There were relapses in 6 per cent. of the cases, but the accepted cure was non-recurrence within four days after stoppage of treatment, when his patients were ordered back to duty. Hyman⁵ recommends irrigating for six to eight days after the discharge stops, even though smears be negative, as is generally the case in one to five days after the institution of the treatment.

On controlling cases by smears and observing the amount of discharge, it was found that no matter how profuse a discharge may be, it practically stops in one to five days or becomes very small in amount and of a white mucoid character, no gonococci being demonstrable. Burning and dysuria, if present, abate and the patient is not only relieved physically but mentally.

The results, in a series of 36 cases, complicated and uncomplicated, in tabular form according to diagnosis and to duration of time for cure, are as shown in the table. Imported acriflavine alone gave the results there recorded.

Two of the acute anterior urethritis cases were first attacks, one responding in 14 days and one in 40 days. Of the acute anteroposterior cases one of the patients was suffering from a first attack, and responded to the treatment in 30 days.

BEHAVIOR OF THE BLOOD CELLS UNDER VARYING CONDITIONS.

BY B. LEMCHEN, M.D.,
CHICAGO, ILL.

PHYSICIAN TO THE CHICAGO STATE HOSPITAL FOR THE INSANE.

Diagnosis	Number of Cases	Average Time of Cure	Mean Time
Acute anterior urethritis	21	13 days. ^a	11 cases cured in 10 days or less
Chronic anterior urethritis	1	This patient had an infected follicle just within the meatus and had two recurrences before this focus of reinfection was discovered having responded promptly to treatment each time, over a period of two months. As he disappeared from view after discharge had stopped for a third time, it is assumed that a cure was effected.	
Acute antero-posterior.	4	28 Days.	Shortest Time. 15 Days.
Chronic antero-posterior with prostatitis	4	41 Days.	10 Days.
Urethritis acute & chronic with prostatitis, vesiculitis, epididymitis.	4	(1) Responded in 3 months. (2) Responded in 4 months. (3) Responded in 2 months with no result. (4) Responded in 4 months.	
Urethritis, acute & chronic, plus stricture.	2	(1) Slight discharge in 20 days. (2) No discharge after 40 days. No discharge after 20 days.	

These cases were controlled by observation of the amount of discharge and by smear; the patients being allowed to go without treatment, irritated by imbibing alcohol and given provocative injection plus massage on a sound. All patients were observed for at least ten days after treatment was stopped, and some were cultured for gonococci.

In conclusion, it may be said that some cases, not included in this series, having had other treatment before acriflavine treatment was instituted, have been fairly uniform in their quick response and good results. In regard to the cases included in this series, I wish to say that the results were more than ordinarily satisfactory and that it seems that acriflavine in a strength of 1:4,000 in physiological saline is, to-day, the best remedy we have for the irrigation treatment of gonorrhea, as may be judged by the records above.

I wish to extend my thanks to Dr. A. Hyman, both for his kind suggestions and help and for allowing me to utilize the records of results obtained in treating cases, in conjunction with him.

50 WEST EIGHTY-FOURTH STREET.

Sclerodermic Arthropathies.—Adrian and Roederer write exhaustively on the arthropathies which develop in the course of scleroderma. Of these there are three groups. In the first the arthropathies are primary, preceding the scleroderma; in the second the two types of lesion are evolved simultaneously, and in the third the joint lesions appear after scleroderma is under way. The authors eliminate all arthropathies due to familiar causes and discuss only such lesions as apparently have a common origin with scleroderma.—*Annales de dermatologie, etc.*

ON Nov. 6, 1915, and April 1, 1916, I reported in the MEDICAL RECORD the results of a study I had made on the cells in the cerebrospinal fluid and blood, stained with benzidin or benzidin combined with picric acid. At that time I found that some of the white cells contained granules, which granules stained blue with the benzidin stain; that some of the white cells (the entire cell including its nucleus) stained blue. With the benzidin stain which cells I called the transitional cells of Lemchen, as they seemed to me to be forerunners of the plasma cells; that some of the red cells did not stain blue with the benzidin stain; that nucleated red cells, both the cell and the nucleus, stained blue with the benzidin stain; that the blood platelets did not stain blue with the benzidin stain, and that fibrin also stained blue with the benzidin stain. The conclusions I drew at that time from my observations were that the white and red cells have different origins, that the platelets have not their origin in the nucleus of the red cells, and that the red cells may take part in the coagulation of the blood and in the agglutinations in the infectious diseases.

Since I wrote those papers several others have appeared in the Medical Literature. One of these is by McJunkin, in the *Journal of the A. M. A.* on Jan. 3, 1920, who states that by adding a polychrome stain to the blood cells after they are stained with the benzidin stain he is able to find granules in some of the white cells, but these are stained brown instead of blue as I found them when I used the benzidin stain alone. MacLins reported in the *Archives of Neurology and Psychiatry* for April, 1920, in the study of brain repair and staining with the benzidin stain, that he found cells that also stained blue with the benzidin stain, which cells he called macrophages. However, the description of the cells shows that they are not identical with the cell that I described on Nov. 6, 1915, but they rightly claim that those cells have their origin in the endothelium and neuroglia cells.

The interesting part of it is that the same macrophages are found also in the cerebro spinal fluid in organic brain diseases, like general paralysis, meningitis, some forms of encephalitis, etc. While the endothelial cells may have their origin in the blood vessels of the meninges or in the meninges themselves, the neuroglia cells must have their origin from without and therefore the choroid plexus is not as impregnable as the anatomists would have us believe. I myself have reported in the MEDICAL RECORD for July 17, 1920, that in influenza the blood platelets are diminished while the coagulability of the blood is increased. Since I have found that when the spinal fluid contains a large number of red cells that do not stain blue with the benzidin stain, if we let these cells stand in a test tube the red cells will clump in a shorter time and the clump will be firmer than when there are only a few or no red cells that do not stain blue with the benzidin stain.

The conclusions to be drawn from those observa-

tions are, in addition to the previous ones, that, in disease at least, the choroid plexus or the blood vessels in the meninges allow cells to pass into the cerebrospinal fluid and that the catalase ferments, to which the cells owe their power of staining with the benzidin stain, in some way prevent the coagulation of the blood during life.

INFESTATION OF A HERD OF SWINE BY HYDATIDS.

By ARTHUR A. RADCLIFFE, M.D.,
WAUKEGAN, ILL.

ON a Southern plantation eighty-seven hogs were being kept in a two-acre pasture, fed all the shelled corn they could eat from self-feeding bins, to fatten them and change their mast-fed fat, which is oily and transparent, to the thicker, white, opaque fat of corn-fed. The man in care of these hogs, who had a *mediocanellata* tapeworm, frequently defecated around the corn bins. Those hogs were all killed within two days, and when the livers of many of them were examined, they all had many hydatid cysts, from 1/8 to 1 in. in diameter. Some larger ones contained a milky fluid which under the microscope showed round bodies from 1/2,500 to 1/1,200 in. in diameter—elongated, flattened at one end, at the other end having a circle of hooklets. The men killing the hogs said that about every liver had the cysts. The plantation store-keeper selected a piece of liver from one of those hogs which he thought did not contain a cyst, and after it was cooked ate it. Later he had the same kind of tapeworm.

Those hogs were taken from a lot of near 3,000, that were born and raised in an uninhabited wooded river bottom, that partly overflowed at times of high water. There was no possible chance of their having become infected there. They were kept in the pasture above mentioned not over two months. The man occasionally went to the R. R. Station and probably got his worm from a lunch in a saloon.

Medicolegal Notes.

Insufficient Evidence of Malpractice—Escape of Tube Into Wound.—In an action for malpractice based on the escape of a drainage tube into the plaintiff's pleural cavity following an operation there was only the fact of the escape of the tube some ten days after the operation and its insertion by the defendant surgeon into the incision made by him, and after the wound had been dressed several times by different hospital nurses. It was held that this evidence was insufficient to support the charge of negligence, which was bottomed only on the manner or sufficiency of the fastenings. The doctor saw the patient about twice a day after the operation. It did not appear that the dressing of the wound was had in the doctor's presence, or that the nurses were not skilled in doing their work. The patient sustained a somewhat different relationship to this doctor, so far as nurses were concerned, that he would sustain if he were a private patient under the charge of nurses selected and placed in charge by the doctor. It was held a pertinent inquiry to ask a witness familiar with the duties of a nurse in a hospital whether it was the duty of the nurses to see that the tube was in and that the stitches were in place at the time they dressed the wound. The jury might well find that the defendant properly fastened the tube and was guilty of no negligence in the manner in which he fastened it, but that

the internes or nurses whose duty it was to dress the wounds were negligent and careless in the dressing, and through this the tube became loosened from its moorings and slipped into the body. The defendant was not charged with any negligence of the nurses in dressing the wound. It was also held that expert testimony as to the malpractice was not necessary where a surgeon, knowing exactly where a drainage tube was located in a patient's body, in an effort to remove it, cut the body at such point as would clearly suggest to the mind of the ordinary layman that the wound was grossly in excess of what was reasonably necessary to reach the tube. For the purpose of negating the claim of the defendant that the plaintiff was not able to take an anesthetic, or to submit to a proper operation to have the tube removed, the plaintiff introduced evidence that a year later he had the tube removed and was able to submit to an anesthetic without suffering any ill effects. It was held that such evidence did not have the intended effect. It is a general rule that a condition shown to exist is presumed to continue until negated, but this rule applies only to permanent and continuing conditions.—*Burriss v. Titzell*, Iowa Supreme Court, 177 N. W. 557.

Choice of Method of Treatment — Negligence of Nurses Will Not Be Assumed.—In a malpractice case the West Virginia Supreme Court of Appeals holds that if a surgeon adopts, in the treatment of a case, a method established and approved by physicians and surgeons generally in the community in which he performs the operation or gives the treatment, at the time thereof, and is not negligent or careless in its application, he is not liable for injuries caused by such treatment. If there are two or more approved methods of treatment of an injury of the kind committed to his care, he may adopt the one which, in his honest opinion, will be the more efficacious and appropriate under all the circumstances, and, in such case, he is not liable for an injury resulting from an error in his judgment, if there be one. He is not bound at his peril to adopt the best method. In such an action it is error to admit evidence of a method of treatment, antedating the treatment involved by a long period of time, and differing materially from the method adopted in the treatment and generally approved and used at the time thereof. The propriety of the use of a plaster of paris cast in the treatment of a compound comminuted fracture of the leg having been established by uncontradicted evidence, it is held error to give an instruction to the jury based upon the hypothesis of negligence in the mere adoption and use of that method, even though an injury has followed which might have resulted from use thereof in an improper manner. If, in the trial of such a case, incompetency of the nurses is relied upon, and no evidence has been adduced for the purpose of proving it, except lack of graduation of the day and night nurses, the head nurse being a graduate, and there is no evidence of any omission of, or any departure from, the instructions given them, nor of any action or conduct on their part resulting in or causing the alleged injury, it is held error to give an instruction founded upon the assumption of evidence of their incompetency and negligence, or either of them.—*Browning v. Hoffman* (W. Va.), 103 S. E. 484.

Statute Authorizing County Support of Hospitals Includes Privately Owned Institutions.—The Michigan Supreme Court holds that the grant of power to a county to support hospitals, in article 8, section 11. of the State Constitution, is limited to those institutions only where "persons suffering from contagious or infectious diseases" are treated, and Michigan Pub. Acts 1909, No. 139, providing for the raising of taxes to support hospitals without such limitation, is invalid in so far as it purports to permit counties to appropriate money for hospitals generally. However, the words "public and charitable institutions" in the said section of the Constitution providing for county support, do not refer exclusively to institutions owned wholly by the municipality, and where a hospital incorporated under Pub. Acts 1903, No. 171, receives "persons suffering from contagious and infectious diseases," it comes within the purview of such constitutional provision, which is self executing, and warrants a county appropriation therefor even though a legislative enactment under the section is invalid.—*Sault Ste. Marie Hospital v. Sharpe* (Mich.), 177 N. W. 297.

REPORT OF THE SURGEON GENERAL OF THE ARMY.

SUFFICIENT time has now elapsed for the compilation of statistics of mortality and disability resulting from the World War. It is possible now to contemplate the great struggle in terms of final results. In his annual report for the year 1920, the Surgeon General of the Army catalogues the final results up to the end of 1919, the latest date for which definite statistics could be stated at the time of formulating the report. Thus, 5,768 military patients whose admissions had been caused by injuries received in battle in Europe remained in Army hospitals in the United States. This number, we are told, was only 2.57 per cent. of the total number of casualties so handled. Not including marines, there were treated in United States Army hospitals during the years 1918 and 1919, 224,089 officers and men of the Army who had been wounded in battle. Of this number 13,691, or 6.11 per cent., died as a result of their injuries; 158,585, or 70.77 per cent., were returned to duty in France; 70,175 cases, or 33 $\frac{1}{4}$ per cent. of all cases other than those which resulted in death, were returned to duty in 29 days or less, the average time for them being 14.17 days. There were returned to the United States for further treatment, 51,813, or 23.12 per cent. of the total. Of this number 20,588, or 39.74 per cent., were ultimately discharged as unfit for military duty, or with 10 per cent. or more disability. In addition to this number, as stated, there were 5,768, or 11.13 per cent., of the cases that were invalidated home, remaining in hospital at the close of 1919. Of the 2,039,329 men who were reported by the General Headquarters, American Expeditionary Forces, to have arrived in France, 110 men out of every 1,000 men were admitted to hospital as a result of battle injury, and 6 $\frac{3}{4}$ died in hospital as a result of those injuries. The Infantry suffered the heaviest loss in wounded and in killed, the former being 215.66 per cent. per 1,000, and the latter 12.77. The Signal Corps was second, with 52.22 wounded and 3.13 dying of wounds.

The classification of admissions to hospital according to military agents responsible for injuries shows that of the total admissions, gunshot wounds accounted for 147,651, or 65.90 per cent.; gases for

70,552, or 31.49 per cent.; and other military agents for 5,886, or 2.63 per cent. Of the 13,691 deaths, gunshot injuries accounted for 12,192, or 89.05 per cent.; gas for 1,221, or 8.92 per cent.; and other military agents for 278, or 2.03 per cent.

Final results (definite disabilities) have been catalogued for 19,768 of the 20,588 men who were discharged for disability, and for the 5,768 who remained in hospitals on December 31, 1919. It is interesting to note, in this connection, the final setting at rest of the persistent and horrifying "first-hand" reports, heard during and shortly after the war, of so-called "basket cases"—unfortunates who had lost both arms and both legs. Not one soldier, the Surgeon General tells us, lost both arms and both legs; nor did one soldier lose both arms or both legs with one other of the opposite extremities. Eleven lost both legs at the thighs, one both legs at the knee, 9 both legs below the knee, one both feet, and 3 one arm above the elbow with one leg at the thigh. In all, 4,403 soldiers lost part of one or more extremities. Counting traumatic cataract as loss of sight, 66 men lost both eyes or the sight of both eyes, 44 lost partial sight of both eyes, and 644 lost one eye or the sight of one eye; 4,790 soldiers had a partial or complete ankylosis of one or more joints. The final results among the 19,768 wounded men catalogued showed 21,696 separate disabilities; 19,140 of these were the result of gunshot missiles and 2,556 of gas. Of the total injuries by the various missiles, the following percentages were catalogued in the final result for each 1,000 injured: Hand grenade, 24.20; shell, 22.04; rifle, 18.30; shrapnel, 15.44; other gunshot missiles, 7.43. Of the total cases gassed, only 2,556, or 3.62 per cent., showed disabilities in the final results; of this number chronic bronchitis accounted for 2,198.

The four diseases that stood at the head of the list as causes of death in the United States also stood at the head of the list in Europe, but with the order changed. Thus, in Europe, the order was: Influenza, 2.00; bronchopneumonia, 1.80; tuberculosis, 1.43, and lobar pneumonia, 1.27. The mortality from these four diseases accounted for almost 80 per cent. of the total deaths from disease in Europe.

It is impossible here to give a full account of the statistical department to date, but the figures given, compared with the numbers involved, and considered in the light of all the circumstances, give us good reason for thankfulness that fatalities and disabilities among our soldiers were relatively so light. Contrasted with the figures of other wars, the statistics given by the Surgeon General should make us doubly thankful, and deeply appreciative of the splendid work of the Medical Department in the case of the sick and wounded during the emergency and in the trying days of post-bellum reconstruction.

NON-TUBERCULOUS SPINA VENTOSA.

CASES of spina ventosa are occasionally encountered which are not due to tuberculous lesions, being the clinical manifestations of either syphi-

lis or a sporotrichosis infection. These morbid processes, in fact, are capable of infecting bone tissue and of determining numerous clinical types, such as hypertrophic osteitis, purulent osteoarthritis, intraosseous abscess, and osteitis of the vertebrae—sporotrichosis Potts' disease. In some cases it may offer the complete clinical picture of spina ventosa.

Chevalier and Darbois have published typical cases. Usually writers who have observed and described chronic sporotrichosis spina ventosa have insisted on the absence of bone lesions and the low grade intensity of the periostitis corresponding to this clinical phenomenon. On the contrary, in the cases described by Chevalier and Darbois the bone and periosteal lesions found by radiography fully justify the term of sporotrichosis spina ventosa, the process occurring in three different types, namely, ossifying periostitis, rarefying osteitis with decalcification with a reticulated or lacunary aspect, and intraosseous abscess. The resemblance to spina ventosa is thus complete, clinically and pathologically.

Hereditary syphilis may likewise give rise to analogous types and the spina ventosa of hereditary syphilis is much more frequent than has hitherto been suspected. The lesion usually attacks the thumb and index finger, often on both hands. The radiographic findings do not differ essentially from those obtained in the tuberculous variety of the process, and the most that can be said is that there is rarely any very considerable detachment of the periosteum and that the lesions are especially those of rarefying osteitis. But the true diagnosis can be made only when other evidences of luetic taint are present and the Wassermann reaction is positive. Consequently, in all cases in which suspicion of syphilis exists a blood examination must always be resorted to. As to sporotrichosis, it has not the same predilection as syphilis and tuberculosis for young subjects and preferably attacks adult individuals. Radiography is therefore not sufficient for making a diagnosis of the nature of spina ventosa, but it is unquestionably a very excellent auxiliary in confirming any hesitancy in diagnosis and in giving indications for proper treatment. Its usefulness is still greater when the results of radiographic treatment are to be controlled and for following the phases and progress of the process, as well as to appreciate the proper time to interrupt treatment. It must be admitted that the esthetic and functional results obtained by Roentgen ray treatment are almost always equal to those of conservative surgery, especially when the case comes under observation in its earlier phases, and in the tuberculous variety of spina ventosa advanced bone lesions with fistula are no contraindications for the treatment. Carried out with those precautions dictated by experience, the Roentgen ray treatment offers no danger from the viewpoint of the integrity of the integuments or the future growth of bones. In the luetic variety a specific treatment should be instituted at the same time.

PODIATRY AS A BRANCH OF MEDICAL PRACTICE.

On January 1, 1913 there became effective in New York State a law which legalized the practice of chiropody. This legislation was sponsored by the New York State Education Department because theretofore the law of 1895 was merely a makeshift to recognize these practitioners practically regardless of their qualifications. The law of 1913 was largely fashioned after the medical practice act and provided surveillance of all chiropodists by the State through its State Board of Medical Examiners. Provision was made whereby in 1921 every intending student of chiropody must have had an academic education equivalent to graduation from a recognized High School; that certain essential medical studies must have been pursued at a standardized School of Chiropody, and that no one, not heretofore legally authorized to practise chiropody, should be licensed so to do unless he or she had passed an examination (covering two days) before the State Board of Medical Examiners. Since then twenty-six of the States in the Union have passed similar laws and within the next three or four years it is reasonable to suppose that every commonwealth in the United States will have legislated similarly.

In 1919 the New York State Legislature broadened the definition of chiropody and incorporated the term podiatry as synonymous with it. Today podiatry, the care of the human foot in health and in disease, is a quasi-profession, bearing allegiance to medicine. Its sponsors have organized a National association, and throughout the country there are teaching schools of podiatry whose faculties are made up largely of licensed medical practitioners. They teach all branches of medicine, the knowledge of which is essential to a proper recognition of the underlying causes of abnormal foot conditions. Foot clinics have been established in connection with these schools where the students, under proper supervision, are taught the practical features of their intended life vocation.

The outstanding feature which rendered it desirable that chiropodists who for centuries have been tolerated in treating human foot ills because the licensed practitioner of medicine considered such practice *infra dig.*, was and is based upon the fact that the public demands this foot care and that no reason exists why it should not be accorded by those properly groomed to practise it. That the recent graduates in podiatry are being thus equipped is manifest. During the past three years the MEDICAL RECORD and other medical journals have published numerous articles on foot lesions from the pens of graduates of The First Institute of Podiatry, which have proven illuminating. Some of these articles have attracted laudatory comments from well-known orthopedists because of their scientific features and the clarity of expression of their writers.

The question naturally arises, why is this legitimate branch of medicine not taught to the students in our medical schools or how comes it that none of the postgraduate medical schools have as yet estab-

lished courses so that practitioners may be taught the principles of podiatry? The economic question which is continuously obtruding itself in medicine finds in podiatry a means of broadening the doctor's sphere. There are thousands of practitioners of podiatry in the United States, and it is stated that their average annual income is fully equivalent to the average annual income of the doctor of medicine. Here then is a by-product of medicine just as many medicines are the by-products of coal-tar, which, like the gnawed bone, has been swept from the table of the satisfied diner, to furnish a feast for one less fortunate.

While some of these Schools of Podiatry are unquestionably doing good work in a worthy cause, others are probably purely commercial institutions, and it is high time that all of them should be investigated by the proper authorities. If something of this kind is not promptly undertaken and if the care of foot ills is not recognized as a legitimate function of the medical practitioner, podiatry will become an entity, reliant upon its own resources, whereas if properly directed it might profitably come into the medical fold.

AN EPIDEMIC OF HICCOUGH.

At a recent meeting of the Paris Neurological Society several members gave their experience with cases of hicough which were remarkably similar and pointed to the fact that a quasi-epidemic was present in Paris. An account of this is given by Logre and Heuyer in the *Gazette des Hôpitaux* for December 18, 1920, xciii, 106. Both sexes were attacked, and as a rule adults predominated. The disease began as a sort of grippy cold, and after the rhinopharyngitis had persisted for 24 to 48 hours the hicough supervened. The latter was persistent and quite rhythmic and so incessant that there was "one hicough for every two respirations" in certain of the cases. Eating was prevented, and some patients vomited. Sleep was poor, light, and interrupted, and some patients hicoughed through their sleep. Occupation was interfered with, necessarily if conversation was required. A magistrate in the discharge of his duties was much embarrassed. The affection got on the nerves of patients but was altogether benign. As a rule in two or three days, and exceptionally in a week, the attack terminated, usually with a spell of deep sleep. Antispasmodics were of little avail. Perhaps hypnotic anodynes exerted some good effect by making the hours of sleep longer, but there is no evidence that the course of the disease can be shortened. One fatality is known to have occurred but particulars are not stated. Usually the condition has been so mild that the patient has gone to the druggist first; and one apothecary relates that he was approached by seven patients in one week who wished "something for the hicoughs." In speculating on the nature of this malady it is known to be contagious from person to person, which would differentiate it from seasonal influenza and epidemic encephalitis. There was no hicough in the grippal pandemic of 1918, but last year this phenomenon was sometimes

seen in myoclonic encephalitis, due evidently to implication of the diaphragm in the clonus. The two forms of hicough are seemingly not related.

The myoclonic form was of grave prognosis and there is no similarity apparent between epidemic encephalitis and the affection under consideration. At the same time the contagious substance is evidently neurotropic, although thus far only for the phrenic nerve. The rest of the picture is decidedly grippal and of the mildest type. Although in some of the patients there was congestion of the base of the lungs, no case of pneumonia has yet been reported. No case seen has been regarded as serious enough to justify diagnostic lumbar puncture. The portion of the phrenic involved, whether nucleus, trunk or terminal ramification is as yet uncertain. The author appears to suggest that there may be some relationship between the congestion of the lower lobes of the lungs and the terminals of the phrenic but does not urge this point. Attempts were made to produce traction on the phrenic and to refrigerate the cervical part of the trunk; results are said to have been "variable."

TREATMENT OF SEASICKNESS.

NOLF's method of treating seasickness, which has been recently published, is reviewed in *La Presse Médicale* for Nov. 6, 1920, xxviii, 81. The older practitioners often sought to produce a hyperemia of the brain, the syndrome being thought due to cerebral ischemia. Among the remedies are certain vasodilators such as caffeine, camphor, and glonoin. Other remedies are given without theory and represent pure empiricism. Seasickness is due to labyrinthine vertigo, or at least comprises that phenomenon, which in many respects suggests a vagotonic component. According to Nolf, seasickness may be closely simulated in poisoning by pilocarpine, muscarine, or eserine. Upon this theory he has made many experiments with atropine and finds that in the majority of cases it is a specific for this affection. In negative results the dose may be too feeble. This should be sufficient to produce the physiological action of the drug—dryness of the throat and acceleration of the pulse. Ordinarily two milligrams of the neutral sulphate in three doses will answer. The treatment should begin before vomiting sets in. The hypodermic use of the drug in the author's experience has given negative results when injected during the status, hence atropine is rather prophylactic than curative. Small doses taken for some days ahead of the projected voyage seem to confer immunity on the specially predisposed. As Cheinisse states, Nolf is not the first who has recently recommended this treatment. In 1919 Cazamian, on the basis of the vagotonic theory, prescribed atropine, and one of his articles was reviewed at the time in the *MEDICAL RECORD*. He used the hypodermic route and gave the drug in advance of the outbreak. Recently Naame has combined adrenalin with atropine, while Pron has given with success before sailing a mixture of belladonna, cannabis indica, and other sedatives. Nolf began his studies on the subject as far back as 1916. The drug was, however, well spoken of as a remedy for seasickness in the early '90s of the last century.

BUBONIC PLAGUE IN FRANCE?

ACCORDING to the daily press it has been officially admitted that cases of this affection have been recognized in Paris. Thus far the medical journals received have said little or nothing on the subject, but in the *Infectious Diseases and Hygiene* number of *La Médecine* (December, 1920, ii, 3) Joltrain, chief of the laboratory service of the university, discusses the disease freely and states that the bubonic type is the only one which has been seen in France, names, places, and dates being omitted. Whenever the plague enters a country we note the same phenomena. Cases are overlooked or regarded as doubtful in the absence of full proofs; diagnosis may be retrospective, the patient having either succumbed or recovered. Of the other clinical forms there are two, the primary pneumonic and the septicemic, the latter being only a hyperacute case of the bubonic type in which death antedates the appearance of buboes. In any suspicious case we should practise hemoculture or if glandular swellings are in evidence diagnostic puncture of the glands. The pneumococcus is often associated in symbiosis in the spleen, buboes, etc., and confusion may result if only one of these is found in the absence of the other; thus, finding the pneumococcus once caused a negative diagnosis of the plague. The latter affection may appear as carbuncles instead of buboes, and such lesions are preceded by blisters. In either case the puncture fluids should be examined for the *B. pestis*. Suppurating buboes may be free from the latter, but contain the familiar pyogenic organisms.

News of the Week.

Travelers Protected Against Water-borne Diseases.—Within the last twelve months the danger to railway travelers of infection with typhoid fever, dysentery, and other water-borne diseases has been reduced to a minimum throughout the greater part of the United States by the cooperation of the United States Public Health Service and the different State boards of health in the testing of the water used on railway trains for drinking and cooking. Within a few months similar protection will be afforded to passengers on river and lake steamers and to ocean steamships sailing from American ports. This work was begun last June and since that time has been carried on in nearly half the States in the Union, in many of which sanitary divisions were lacking. In nearly all of these such bodies have been or are being organized, and in about half of them surveys have been made of many or all important water supplies, most of which have been found safe for use on trains. Periodic examinations will of course be made. It is believed that the information obtained will permit the United States Public Health Service to frame regulations to govern the water supply of all vessels on American lakes and rivers or sailing from American ports..

Report on War Disabled.—A report submitted by Mr. La Porte, Assistant Secretary of the Treasury, which is based on estimates made by the Public Health Service, declares that 40 per cent. of the discharged disabled veterans of the world war are

suffering from some form of mental derangement. Patients of all classes in the Public Health Service hospitals are increasing, according to Mr. La Porte, at the rate of 1,000 a month. On September 10, 1919, there were approximately 5,250 patients in the care of the service, while on January 1 of this year the number had increased to 22,292. Of these patients, 19,019 were war risk insurance patients, of whom 7,586 were suffering from tuberculosis, 5,743 were general medical and surgical patients, and 5,690 were suffering from mental disorders. It is believed that the peak as regards the number of patients will not be reached for ten years, and that when it is reached there will be from 30,000 to 35,000 patients requiring hospital care.

Dirt Plague and Suicide in Hungary.—A report from Budapest states that Hungarians are suffering from an epidemic of carbuncles, and that the hospitals are overcrowded with patients. Professor Arthur Verebely attributes the disease to the lack of soap and linen and says it might be called "the plague of misery and dirt." In Budapest the suffering from cold and hunger is so intense that, according to an official statement, suicides due to these causes average fifteen daily.

Bill to Control Chiropractic.—Senator Fletcher of Florida introduced a bill on January 6 for the regulation of chiropractic in the District of Columbia. The bill proposes to establish a board of five members, representing the various schools of the profession, for examination of applicants to practice chiropractic.

Chicago Opens Drive on Narcotic Drugs.—A campaign to stamp out the illicit trade in narcotics was started by Federal authorities on January 13. Warrants were issued for twenty physicians and druggists, who, the Federal agents say, have been working together in prescribing and filling prescriptions in violation of the anti-narcotic act.

Amendment to Volstead Act.—An amendment to the Volstead act which would prohibit the sale of liquor containing less than 45 per cent. alcohol has been introduced into the House of Representatives by Representative Vare of Pennsylvania. In submitting this amendment Representative Vare stated that complaints had come to him from druggists that manufacturers of liquor as well as wholesalers and jobbers are selling adulterated liquor for medicinal purposes and he urges that in the interests of the public this should be stopped.

War Achievements in Surgery Reviewed.—A conference, conducted by Lieut.-Col. William L. Keller, for the purpose of demonstrating method of treatment and results in war surgery was held at Walter Reed Hospital, Jan. 8. About fifty convalescent patients were exhibited, while members of the medical corps gave a demonstration of the application of standard war splints employed in the transportation and treatment of fractures and of methods of treating bony defects and deformities following war wounds. Among those who took part in the program were Major Marion R. Mobley, Major Tom S. Mebane, Major Henry K. B. Hufford, Major Norman T. Kirk, Major John S. Gaul, and Lieutenant Philip L. Cook. Following a luncheon given to the participants by the Hospital authorities, Dr. Joseph C. Bloodgood of Johns Hopkins Univer-

sity gave a lecture on the subject of bone tumors.

Peking Union Medical College.—In announcing the appointment of Dr. Henry S. Houghton, who has spent fifteen years in China, recently as a member of the staff of the China Medical Board and Peking Union Medical College, to the directorship of this institution, the Rockefeller Foundation describes the work being carried on there. In seeking to aid Western medicine in China, the China Medical Board of the Rockefeller Foundation is endeavoring to provide pre-medical education, undergraduate courses for physicians, graduate study for investigators, laboratory workers, teachers, and clinical specialists, short courses for private practitioners and missionary doctors both foreign and Chinese, medical research, especially in Far Eastern problems, standardized hospitals, education of the public in modern medicine and public health, and the fostering of professional ethics through the development of character and idealism. The institution now has a new fireproof medical school and a 250-bed hospital, the older buildings being used as laboratories and pre-medical school lecture rooms. Women are now admitted to the courses on equal terms with men, and to thorough courses in nursing. The faculty, numbering forty, includes a number of Chinese scientists. It is expected eventually to turn the institution over to complete native management.

Fight Epidemic of Colds.—By order of Dr. George W. Morse, head of the new medical department of the Massachusetts Institute of Technology, members of the faculty are to send all students who are detected sneezing or coughing to the school clinic where they can be taken care of. This order is the result of an epidemic of colds, and not only those who sneeze and cough but those who show symptoms of any kind are to be made to call at the clinic at once.

Bill to Subsidize Prussian Midwives.—A bill has been introduced into the Prussian National Assembly which provides that obstetricians shall henceforth enjoy a semi-official status and receive, besides their minimum fees, an annual salary of 3,600 marks and have each her own exclusive sphere of employment. The measure was introduced by the Socialists on the ground that 100,000 children had perished because the proletarian mothers had been unable to obtain proper advice and help from midwives.

Medical Examination of Jail Inmates.—The New York State Prison Commission recently adopted a resolution urging the sheriff and board of supervisors of each county in the state to make provisions for the medical examination of every person admitted to a county jail and to arrange that all such persons afflicted with venereal disease, tuberculosis, or other communicable diseases may be segregated.

Diphtheria Increases in New York City.—The *Weekly Bulletin* of the Department of Health calls attention to the fact that the prevalence of diphtheria in New York City, during November and December, 1920, was considerably above that of last year and that of the five-year average. During the last two months of 1920 there were 3,544 cases of diphtheria as against 3,004 for the same period of 1919, and 211 deaths during this period as compared with a five-year average of 175 deaths for

these two months. The Department of Health appeals to all physicians to cooperate in special measures to control the spread of this disease: First by immunizing all children who have been exposed to diphtheria, and, second, by urging all families not directly exposed to the disease to be Schick tested.

New York Quarantine Station Transfer Completed.—The deeds of conveyance transferring from State to Federal control the Quarantine Station of the Port of New York have been sent to Washington. The property transferred includes eighteen acres and buildings at Rosebank, Staten Island, Hoffman and Swinburne Islands, and several boarding and fumigating tugs. The Federal Government has paid \$1,395,275 in compensation.

Women's League to Push Child Welfare Work.—The League of Women Voters of New York State has abandoned the women's welfare bills which it has been supporting at Albany, and announces that a large part of its work this year will consist in promoting child welfare work. This feature of the program is in the hands of Dr. S. Josephine Baker, chairman of the league's child welfare committee.

Fund for Study of Convalescence Problems.—The Sturgis Research Fund of the Burke Foundation, White Plains, N. Y., has been established with endowment by the president, Mr. Frank K. Sturgis. The income is to be used in research in cardiac and allied convalescent problems.

Sanitary Engineers Organize.—The sanitary engineers of the various State Departments of Health have recently organized a conference of State sanitary engineers which will meet annually with the Conference of State and Provincial Boards of Health.

Surgeon Operates Though Insane.—According to a special cablegram to the New York *Herald*, Herr Gebherd, a surgeon of Schwerin-Mecklenburg, has continued to perform surgical operations of a serious nature though evidently insane for a long time. Since Herr Gebherd has been certified to be insane and taken to an institution it has been learned that he has performed many extraordinary operations in his demented state, among them being the case of a soldier whose arm was unnecessarily amputated, and a woman whose ear was cut off because she was suffering from inflammation of that organ.

Dr. George Gray Ward, Jr., has removed his offices to 48 West Fifty-second Street, New York City.

Dr. Henry Helmholtz, assistant professor of pediatrics in Rush Medical School and chief of medicine in the Children's Memorial Hospital, Chicago, has gone to Rochester as professor of pediatrics in the Mayo Foundation and head of the section on pediatrics in the Mayo Clinic.

Dr. Henry S. Houghton, who has spent nearly fifteen years in China, has been appointed director of the Peking Union Medical College, conducted by the Rockefeller Foundation and six missionary societies.

Captain J. F. Wallis of the Army Medical Museum, founder of the art of presenting diseases and wounds in wax and paint, described by Major Shufeldt in the *MEDICAL RECORD* of Oct. 19, 1918, has been retired from Government service and returned to civil life.

Dr. Alfred Gordon of Philadelphia has been elected a member of the Neurological Society of Paris, France.

Medical Editors Knighted.—Dr. S. Squire Sprigge, editor of *The Lancet*, and Dr. Dawson Williams, editor of the *British Medical Journal*, recently received the honor of knighthood.

Harvey Society Lecture.—Sir Arthur News-holme, M.D., resident lecturer in charge of Public Health Administration, School of Hygiene and Public Health, Johns Hopkins University, will deliver the sixth Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, January 29, at 8.30. His subject will be "National Changes in Health and Longevity."

Public Health Service Transfers Tuberculosis Patients to East.—The United States Public Health Service announces that all its hospitals in the semi-arid Southwest are overcrowded with tuberculosis patients and the influx of others from the Eastern States continues so great that the Public Health Service has been forced to transfer patients from Tucson, Ariz., and other western hospitals to sanatoriums near Asheville, N. C., and elsewhere in the East. More than five hundred tuberculous subjects in Tucson are unable to gain admission to a sanatorium. Surgeon-General Cumming has again renewed his warning against tuberculosis patients going to the Southwest on their own initiative.

Ships at Sea to Get Medical Advice by Radio.—By an arrangement between the Seamen's Church Institute of New York and the Navy Department, mariners have been trained so that if called upon to treat a serious case of illness or accident at sea they can carry out instructions communicated to them by radio from the physician in charge at the Seamen's Institute. The new emergency radio call for medical help is "K D K E." It is to take its place with the international S O S of all vessels in distress, and means that individual life is in danger and assistance is being asked.

Bill to Consolidate Government Relief Work.—At a hearing before the House Commerce Committee, on January 7, a number of physicians supported the Rogers bill, which proposes to consolidate into one bureau the Government agencies dealing with relief for ex-service men. Dr. Thomas W. Salmon of New York, in urging the passage of the bill, declared that so far not a cent appropriated by Congress for the care of war veterans suffering from disability or wounds incurred in the service had been spent for hospitals for the treatment of the insane. He stated that one-third of the ex-service men receiving treatment at Government expense were neuropsychiatric, and six of each ten men so affected were insane. He deplored the present policy of the Government in sending insane veterans to local asylums, almshouses and sanatoriums operated for private gain. As the result of this method some of these men, Dr. Salmon stated, were lurking at home, afraid to come forward, and were getting worse all the time. Dr. H. A. Pattison of New York, Supervisor of the Medical Service of the National Tuberculosis Association, also supported the bill.

Red Cross Health Work.—The American Red Cross Executive Committee, according to an announcement made by Dr. Livingston Farrand,

Chairman of the Central Committee, has appropriated \$5,000,000 from the society's reserve fund to carry out its program of furnishing desperately needed medical assistance to children in Europe. The first annual report of the Health Service of the Atlantic Division of the American Red Cross gives a detailed account of its health program now in operation in New York, New Jersey, and Connecticut. Chief among its activities in these three States is the establishment of twenty-six Red Cross health centers, of which seventeen are in New York, six in New Jersey, and three in Connecticut. Various phases of health service have been inaugurated in sixty-one other places. The objects of the health service, as stated in the report, are to support and, if need be, supplement approved work of official and volunteer health agencies.

Epidemic of Hiccoughs in Budapest.—An epidemic of hiccoughs has spread to such an extent in Budapest that physicians are unable to cope with it. The patients are said to be unable to eat or sleep, and in some instances it takes two to three weeks for the malady to run its course. As yet no fatalities are reported.

Experiments in Food Preservation.—Speaking before the American Society of Biological Chemists, Dr. M. J. Rosenau of Harvard University described experiments conducted under his direction to determine how food-canning plants can prevent botulism or similar poisonous organisms from getting into olives, fish, and other preserved foods. The investigation has been directed to ascertaining what causes the growth of these germs, what will kill them, and what will prevent their germination. Speaking before the same organization Dr. F. R. Moulton of the University of Chicago, predicted that the future developments of science and discovery will change the universe beyond our present comprehension, and that radium and electricity will become relatively unimportant in comparison with the greater discoveries to come.

War Against Blindness.—A world-wide war against preventable blindness was inaugurated in Washington on January 10 by a conference at which Miss Winifred Holt of New York made the principal address. A Washington committee has been formed to cooperate with the New York Association for the Blind in carrying on the work. Co-operating committees are to be formed in other large cities. Foreign governments were represented at the Washington meeting.

Obituary Notes.—DR. ROBERT JARED BLISS HOWARD, a well known British physician, died in London on Jan. 9. He was educated at McGill University, at Montreal, and at the London Hospital. He was a Fellow of the Royal Society of Medicine.

DR. JAMES J. O'DEA, a graduate of McGill University, in 1859, died at his home in Stapleton, Staten Island, N. Y., on January 12, at the age of eighty-four years. He was a member of the staff of the Staten Island Hospital.

DR. LEO SCHNEPP of New York City died at Dr. Combe's Sanitarium on January 11. He received his medical degree in Budapest in 1874.

DR. FRED W. EASTMAN of Lees Summit, Mo., died in Bolivia, on January 5 or 6, at the age of thirty-

seven years. He was a graduate of the University of Missouri and Columbia University Medical School, served in the United States Medical Corps overseas, and at the time of his death was physician in charge of the medical corps attached to the Guggenheim Brothers mining forces in Bolivia.

DR. THOMAS NOTLEY McLAUGHLIN of Washington, D. C., died after a brief illness, on January 3, at the age of sixty-one years. He was graduated from the George Washington University in 1882 and was a former president of the Medical Society of the District of Columbia.

Obituary.

WILLIAM ALLEN BARTLETT, M.D.

NEW YORK.

IN the death of Dr. Bartlett which occurred in this city on January 5, 1921, the community lost a valued and patriotic citizen, and the medical profession an able and conscientious practitioner.

Born on September 17, 1858, Dr. Bartlett was graduated from the College of Physicians and Surgeons in 1881. He received an appointment to the House Staff of the New York Hospital, where he served on both the Medical and Surgical Divisions. In 1883 with high ambition and keen enthusiasm, he entered upon his professional career; and from that time until June of last year, he devoted himself continuously to the practice of internal medicine. He was a man of studious habits, high ideals, and unbounded enthusiasm. Quick to appreciate the value of new discoveries and improved methods, he always kept abreast of the times by adopting the many aids to diagnosis and treatment which, during the past three decades, have resulted from the vast amount of scientific and laboratory research. Although of a sanguine nervous temperament and possessed of a vast amount of energy, Dr. Bartlett was essentially a modest man, and never employed even the ordinary legitimate methods of self-advertising which are thought to count so much in professional success. He rarely attended medical meetings, contributed scantily to current medical literature, and aspired to no hospital or teaching position.

The outstanding characteristics of his practice seemed to his colleagues to be painstaking observation, accurate diagnosis, and a willingness to devote any amount of time and effort to the welfare of his patient. Few general practitioners were so prompt to recognize a surgical indication or so insistent on the necessity for early operation in suspected malignant disease or for measures to arrest or combat a spreading infection.

In addition to his professional activities, Dr. Bartlett was always a lover of art. He was devoted to out-of-door life, was especially fond of the sea, and during his later years, he developed the rare gift of being able to reproduce on canvas the beauty of landscape and sky and ocean as he observed them during his holiday outing. Although he never enjoyed the advantages of systematic instruction, his natural appreciation of color and form enabled him, during the last decade of his life, to produce a number of paintings and charming sketches, which have afforded much pleasure to his large circle of friends and admirers.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, December 24, 1920.

Births and Deaths.—The return of the Registrar-General for the week ended December 4, shows that in the ninety-six great towns of England and Wales the births registered during the week numbered 7,388, and corresponded to an annual rate of 20.8 per 1,000. The deaths among the civilian population numbered only 4,494, and corresponded to an annual rate of 13.2 per 1,000. In the three weeks ended November 13, 20, and 27 the rates had been 13.4, 12.8, and 13.5 respectively. The infant mortality was 98, against 85, 87, and 92 in the preceding three weeks. For London there were 1,921 births corresponding to a rate of 22.1 per 1,000, and 1,091 deaths of civilians, corresponding to a rate of 13.1, as against 14.9, 13.6, and 14.1 per 1,000 respectively, in the three weeks ended November 13, 20, and 27. The death rate in the four weeks ended December 4 averaged 13.9 per 1,000. The infant mortality was 78 as against 63.80, and 75 in the preceding three weeks.

National Health Insurance.—The first valuations, disclosing the results of the six years' working of National Health Insurance, were issued by the Ministry of Health recently. They show that the financial basis of the act has proved to be more than sufficient, as, in hundreds of branches of the Ancient Order of Foresters substantial surpluses are certified by the Government actuary to be available for increasing the rate of sick benefit from seven shillings and six pence to ten shillings and the maternity benefit from forty shillings to fifty shillings.

Ministry of Health Bill.—The Ministry of Health Bill has been rejected by the House of Lords after having been passed by the House of Commons against considerable opposition. The debate on the bill in the Upper House was brief, the main ground of objection to passing it being that it was unfair to expect the members to deal with so complicated a measure in the few remaining days of the session, when it was impossible for them to submit it to that process of improvement to which they subject measures sent up to them from the House of Commons. In a leading article in the *Lancet* of December 18, it is pointed out that its composite character was against it from the first. Clauses 10 and 11, around which medical interest especially centered, embodied an attempt to deal with the questions of incipient mental disease and of hospital accommodation in accord with the really urgent needs of the moment, without too heavily committing the future. One great objection against the bill was that the measures proposed would cost a considerable amount and another objection was that it was of a complicated nature. With regard to hospital provision the insistent necessity of the day, which was to some extent considered in the bill, the hope may be expressed that the committee appointed by Dr. Addison to investigate the financial position of voluntary hospitals will do their work as quickly as possible. The need is pressing.

Twenty Thousand Pounds for London Hospitals.—Mr. D. B. Gibb has just left practically all the property amounting to £23,000, of which he died possessed, to various London hospitals. These are St. Thomas's, Guy's, Bartholomew's, The Middlesex, The London and Earlswood Asylum.

Memorial to Dr. Lyster.—It will be remembered by the readers of these letters that some few months ago the death of Dr. Lyster, the director of the Middlesex Hospital X-ray Department, who fell a victim to his devotion to science, was recorded. The chairman of the Bolingbroke Hospital at Wandsworth, near London, has published a letter recently in the public press which reads as follows: "Nearly forty years ago the late Dr. Lyster was appointed resident medical officer at Bolingbroke Hospital, and it was at this institution that he began his experiments with the x-rays. To his unremitting devotion to this work the present-day efficiency of the x-ray as a curative and remedial agent is very largely due. Dr. Lyster's studies assisted in perfecting that which proves day by day to be of incalculable benefit to mankind, but in the end his services to science have cost him his life after many years of intense suffering. It is suggested that a memorial to such a public benefactor could not be provided in a more appropriate place than the hospital in which his experiments were instituted, or that no form of public appreciation under the circumstances could be more fitting than an x-ray apparatus and equipment, which would enable his great work to be carried on."

A memorial certainly ought to be raised in memory of Dr. Lyster. He probably did more than any one man in this country to advance the knowledge and scientific application of the x-rays for medical and surgical purposes.

Surgical Treatment of Malignant Disease of the Colon.—At a meeting of the Medical Society of London, held on December 6, last, surgical treatment of malignant disease of the colon was discussed by some of the best known British surgeons. Sir Berkeley Moynihan opened the discussion by reading a paper on the subject. He described various symptoms which usually herald the presence of a tumor in the abdomen or the occurrence of some form of intestinal obstruction, subacute or acute. With regard to radiological examination, it was pointed out that a bismuth or barium meal gave little help. So far as operation was concerned, he laid stress on the mobilization of the colon as the first step. The amount to be removed was such that operations could now be standardized. If a growth appeared in any part of the colonic midgut the whole of that was removed. When the growth was in the distal part of the transverse colon or near the splenic flexure the left half of the transverse colon and almost the whole of the descending colon were removed after mobilization. Growth in the descending colon necessitated its entire removal and growth in any portion of the pelvic colon, the removal of the greater part or the whole of this with perhaps the termination of the descending colon. If the growth was in the middle of the transverse colon it was only necessary to excise widely. Subsequent anastomosis of the bowel could be obtained

by three methods: (1) End to end, (2) Side to side, and (3) End to side. Moynihan never employed the end to side method. End-to-end opposition he regarded as quite satisfactory. A side-to-side anastomosis, he thought, was probably the safest for any but the very skilled operator, and was just as satisfactory. After the anastomosis had been completed the question would arise as to whether the intestine should be opened at some point proximal to the new junction to give vent for a few days to flatulence or liquid feces. In recent years he had abandoned removing the appendix and inserting a small tube in the cecum, and instead had stretched the anal sphincter. Sir W. Arbuthnot Lane dealt first with the causation of cancer of the large bowel, showing that the factors which determine its existence are three, viz., traumatism, a degenerative process in the tissues, which is usually the result of intestinal autointoxication and less frequently of syphilis, and thirdly, an unknown factor. He pointed out that the nature of the surgical interference must depend on a large number of conditions, such as the locality and extent of the growth, the condition of the intestine at the time of the operation, especially as regards accumulated contents, the vitality of the individual, the invasion of adjacent viscera and abdominal wall, the presence of secondary growths, and many other important factors. He urged radical measures when possible as being frequently the most easy to perform, as reducing the risk of recurrence and as improving the health and happiness of the individual. Mr. Garnett Wright emphasized the importance of early diagnosis, and said that cases of colonic growth were rarely seen by the surgeon before they had been greatly complicated by acute obstruction. Mr. J. P. Lockhart-Mummery said that cancer of the colon was one of the least malignant forms of cancer in the alimentary tract. It was the slowest to spread to surrounding structures, and when freely removed there was less danger of recurrence than with any other form of cancer of the intestinal epithelium. If cancer of the colon was to be successfully treated it was most important that the surgeon should get the case at an early stage, and, therefore, early diagnosis was of the utmost importance and should be made before the obstruction had occurred, and before there was palpable tumor in the abdomen. The most valuable aid to diagnosis was the sigmoidoscope.

Obituary.—A cable received at her home at Dover a few days ago recorded the death at Nazareth, Palestine, of Miss Edith Johncock, Matron of the British Hospital at Nazareth. Miss Johncock was a prisoner of the Turks for several years of the war, but remained in charge of the Nazareth Hospital for a great part of the time, attending on British and Turkish wounded prisoners of war.

Mechanotherapy, Unregistered as Physician, Cannot Recover for Services.—The Missouri Supreme Court holds that under Missouri Rev. St. 1909, sections 8311-8315, making it unlawful and an offense to treat the sick without being a registered physician, a mechanotherapy, not being such, cannot recover for services rendered in treatment of ailments and diseases of the human body.—*O'Banno v. Widick* (Mo.), 220 S. W. 853.

LETTER FROM BELGIUM.

(From Our Own Correspondent.)

LIÈGE, December 20, 1920.

Status of Medical Science in Belgium.—Science in Belgium has made strenuous efforts to regain the energy which it had before the great cataclysm but in general the universities are suffering from an intellectual apathy due to two causes. The first of these is the lack of material. The Germans stole much and they broke even more, and the material which was destroyed has not been replaced to any extent. The second, and this is to be deplored, is a general haste to obtain the final diploma. Serious work is rare and the laboratories are doing little. Those formerly in the service enjoy special favors permitting them to go up for examination in one branch at a time and at any time they desire, even when the Board of Examiners is not in session. They take advantage of this naturally, for having suffered so much during the war they want to profit a little from peace. But this utilitarian tendency has done great injury to medical science which demands that its votaries shall be fervent and disinterested and consecrate themselves to its service *perinde ad cadaver*. I shall hope to return to this subject in a future letter.

Surgical Education.—The creation of a surgical and experimental laboratory at Liège is announced. It is an annex to the Military Hospital and is due to the initiative of the Commandant, Dr. J. Voncken, Chief of the Surgical Service at this hospital. This is the first undertaking of the kind in Belgium, at least as regards the establishment of a laboratory where all the students can gain instruction and benefit from the practical teachings there given. Young military medical students are gathered together in groups of four or five in which are performed various practical operations on animals which are progressively more delicate and more difficult, beginning, for example, with simple costotomy and going on to operations on the biliary passages and abdominal surgery. The results obtained by this method of teaching are excellent as regards the development of personal initiative, manual skill, sang froid, and experience.

Honors for Professor Bordet.—Prof. Jules Bordet, Director of the Pasteur Institute of Brussels and Professor at the University of the same city, has just been awarded the Nobel Prize for 1921. His notable work on Immunity is what has gained him this distinction. All his works on this subject during a number of years past have now been collected in his "Traité de l'Immunité dans les Maladies Infectieuses," which was published by Masson in Paris early this year. On Saturday, December 18, the recipient of this prize was fêted by the Royal Academy of Medicine and by the entire scientific body in Belgium, which rejoiced in the honor conferred upon one of our chief citizens. Many French and English scientists were present assisting in this celebration. Following the meeting of the Academy, a solemn session of the Free University of Brussels was held in the Palais d'Egmont in his honor. Among those present were M. Max, Mayor of Brussels, who presided and also

MM. Roux, director of the Pasteur Institute of Paris; Calmette, assistant director of the same institute; Walter, professor of the University at London, most of the Belgian Cabinet, the Ministers of Sweden and of the United States, as well as the King and Queen of Belgium. Many speeches laudatory of Prof. Bordet's work were delivered.

Prof. Bordet, in acknowledging these eulogies, first thanked the King and Queen for their presence, and then expressed his gratitude to the Nobel Committee and all his friends who had organized this celebration. After the solemn assembly the Mayor of the city presented M. Bordet and his family to the King and Queen and to the others present. A grand banquet completed the celebration where numerous speeches of congratulation were delivered and were feelingly replied to by Prof. Bordet. Prof. Bordet, after having described the impressions which he brought back from his journey to America, spoke with appreciation of the intervention of the Americans in the war, in which they had come to the defense of humanity, and alluded to the linguistic question, saying that the Americans who were not disturbed by this question, having apparently settled it satisfactorily, might perhaps be surprised to learn that there was a small country in Europe which an attempt was being made to divide on this very language question.

2. Sliding Hernia.—Edward H. Risley.
3. Torsion of the Fallopian Tube. Sam S. Dearborn.

2. **Sliding Hernia.**—Edward H. Risley calls attention to this condition, only 36 cases of which were found among 2200 cases of hernia at the Hospital for Ruptured and Crippled. Hernia *par glissement* of the French, or "land-slip of the colon" (cecum or sigmoid) of Treves may be found at either the inguinal or femoral openings. It may occur in children, where it is usually congenital, or in adults, where it may be either congenital or acquired. When one suspects a sliding hernia he should open the sac as high up as possible in order to be able to get into the peritoneal cavity at all, and also to avoid cutting into the intestinal wall, which may form a portion of the lower part of the sac. One should not attempt to dissect the sac free from the colon, as this is practically impossible to do, and much injury to the blood supply may result. Avoidance of any injury to the nutrition of the gut is of greatest importance in these cases.

1. **The Familial Distribution of the Migraine-Epilepsy Syndrome.**—J. Arthur Buchanan, having noted a high percentage of migraine in the study of the epileptic, was led to the investigation of a series of epileptics in which the family history contained a definite statement

of the number of children, the presence or absence of migraine in the family, and the presence or absence of epilepsy, with a numerical statement of the number affected with either condition. Forty-six epileptic families were studied from the viewpoint of the distribution of epilepsy considered as a manifestation of the migraine factor, and in order to learn the heritage of the children when no history of migraine had been found. The families with epileptic parentage were also studied in order to learn if they followed the same general principle. Either the father or the mother of thirty-five patients (75 per cent.) had migraine, six patients (13 per cent.) had no knowledge of migraine or epilepsy in the family, and five (10 per cent.) fell in the heterozygote parentage group. The forty-six families studied consisted of 262 children, of whom 198 were normal, and sixty-four had epilepsy or migraine, giving a mendelian ratio of 3.09 to 1. This ratio is so nearly that obtained previously for migraine alone that they can be considered identical. Forty-four (68 per cent.) of the sixty-four children had epilepsy, and twenty (31.2 per cent.) had migraine; of the latter two were the offspring of an epileptic woman mated with a normal man. Thirteen (29 per cent.) of the forty-four epileptics had migraine as an alternating, preceding, or combined condition. The only patients with so-called arrested epilepsy had migraine as a replacement condition. In the study of the crossing of two pure strains of migraine it was found that all the children from such matings had migraine. One family was found in which a woman with migraine was mated with a man with epilepsy. If epilepsy is considered a manifestation of the same basic condition as migraine, all the children in this family would be expected to have either migraine or epilepsy. All had migraine; in addition one had epilepsy, which alternated irregularly with the attacks of migraine.

7. **Traumatic Intramuscular Ossification.**—Russel F. Madden reports a case and discusses the pathology, biology, and diagnosis. Concerning the treatment he holds that, unless serious disability exists and persists unimproved by active and passive exercises, surgery is contraindicated. If operation is decided upon, the physiology of bone must be remembered. Simple excision is almost certain to be followed by recurrence, because the normal periosteum has been torn loose and no longer fulfills its function as a limiting membrane for osteoblasts. If not operated upon, the mass usually ceases to grow after a time and may even become smaller, owing to reabsorption of bone similar to that seen in some cancellous osteomata. Treatment with radium, the röntgen ray, or potassium iodide, may possibly accelerate this process of consolidation, and does no harm if properly controlled. The patient should be encouraged to exercise in an attempt to restore the normal range of motion. Very frequently vigorous exercise leads to complete functional recovery after a considerable lapse of time.

2. **The Fundamental Classification of Diseases by the Basal Metabolic Rate.**—Walter M. Boothby gives the

following summary of the discussion: 1. The basal metabolic rate is a measurement of the heat production in a person under standard conditions. 2. Like the temperature, the metabolic rate is a measurement of certain heat phenomena inherent in the living organism. 3. The basal metabolic rate differentiates diseases into three fundamentally distinct groups: those with normal basal metabolic rates (a normal heat production); those with increased basal metabolic rates, and those with decreased metabolic rates. 4. The "normal" standard of the basal metabolic rate is not exact, yet the comparatively small "normal" variation, compared to the wide range of pathological variation, admits of fully as accurate grouping of diseases as does the body temperature. 5. It is to be hoped that the value of basal metabolic rates will not be discredited by carelessness in technique and a failure to appreciate the necessity for carrying out all the technical and physiological details requisite for obtaining accurate basal metabolic rates.

6. **Prophylactic Inoculation Against Yellow Fever.**—Noguchi and Pareja consider that sufficient grounds for the possibility of establishing a prophylactic vaccination against yellow fever are furnished by the facts that (1) a person acquires a state of complete immunity enduring for a period of years after recovery from an attack of yellow fever, and (2) the serum of such a person, and also of guinea-pigs once inoculated with the blood of yellow fever patients, contains varying amounts of antibodies against *Leptospira icteroides*. They detail the experiments which show that such vaccination is a distinct possibility. From the results of vaccination in guinea pigs they conclude that when sufficient quantities of the killed culture are given, these animals are usually rendered resistant to a subsequent infection with *Leptospira*. The degree of protection, however, is not strictly proportional to the amounts of the vaccine inoculated. In the vaccination of human beings the results thus far are distinctly encouraging. It is realized, however, that many more observations will be needed before a final decision of its value can be arrived at.

9. **The Urine in Syphilis.**—Klauder and Kolmer review the knowledge that has been accumulated concerning the laboratory aspects of the urine in syphilitic infection, in this report of laboratory studies, including the Wassermann reaction, in sixty cases. They summarize in part as follows: The urine was examined in forty-three cases of untreated primary syphilis, the duration of which was from a few days up to the time of cutaneous manifestations. Urinary abnormalities were present in three cases. The urine was examined in forty-six cases of untreated secondary syphilis. Urinary abnormalities were present in four cases. The positive cases all showed albumin and granular casts, excepting two in which casts were absent. In two cases, red blood cells were present. The albumin consisted of a trace, except that in two of the secondary cases a light cloud was present with many granular casts, and in one red blood cells. The urinary abnormalities disappeared after treatment with arsphenamine and mercury. The urinary abnormalities in secondary syphilis are regarded as due in all probability to an invasion of the kidney by *Spirocheta pallida* rather than due to syphilotoxins—which is the explanation usually given. The clear blood serum and the urine, from the same patient, were mixed for the presence of precipitin, or precipitogens in serum or urine. The serum and urine of twenty acute untreated secondary cases were tested in this manner. The results were negative in all. Either the antibody is absent in the serum, or the antigen from the urine, or both may be absent, as indicated by the results. Clinical and experimental observations show that mercury is considerably more nephrotoxic than arsphenamine or neosarsphenamine. In the conjoined intensive treatment of mercury and the arsenicals, the nephrotoxic action of mercury may retard the elimination of arsenic and in this way cause untoward effects of arsenic. In view of this possibility, conjoined intensive treatment with mercury and the arsenical preparations is not advised. The Wassermann reaction was performed with the urine of sixty patients with syphilis in the different stages of the disease, many presenting acute symptoms and being untreated. Every patient yielded a positive blood Wassermann reaction, the majority of reactions being

strongly negative with three different antigens. Of the sixty cases, the urines in but two yielded positive reactions. Complement fixation tests with urine are exceedingly liable to yield falsely positive results, owing to the highly anticomplementary activity of the urine. Anticomplementary activity varies with individual specimens. It is greater in old specimens than in fresh ones. Heating in a water bath at 56° C. for thirty minutes removes only a slight amount of the anticomplementary substances. *Spirochæta pallida* may be found in the urine of syphilis in the acute stage of the disease. There is no characteristic feature in the urine of paroxysmal hemoglobinuria of syphilitic origin which serves to differentiate it from the same condition due to other causes. Results with urinary tests for syphilis were of no value as a means to the diagnosis of syphilis.

1. An Experimental Investigation of *Spirochæta Duttoni*, the Parasite of Tick Fever.—Maj.-Gen. Sir William B. Leishman, in concluding this detailed discussion, gives the following as the probable train of events. Starting from a patient suffering from tick fever, whose blood contains *S. p. duttoni*, and who is bitten by a tick, the spirochetes taken into the tick's intestinal tract gradually lose their motility, and many undergo structural changes such as the formation of granules and the extrusion of buds. They do not multiply in the tick in this form and rapidly disappear, few being left by the eighth to tenth day. The granules are either extruded during life or, more probably, are liberated by the breaking down of the spirochetes, either in the gut or within the tissues into which they have wandered. These granules present themselves as small clumps embedded in a homogeneous matrix, and are found chiefly in the cells lining the Malpighian tubules and in the genital tissues. They persist throughout the life of the tick, and are to be found at times in the intraovarian eggs, as well as in the young nymphs hatched from the eggs. In the young nymph the granules are capable of multiplying, sometimes to an enormous extent. The buds formed on the ingested spirochetes contain similar granules, and when separated from the parent spirochete are difficult to distinguish from the other granule clumps. They are rare in comparison with the number of granule clumps arising from the segmentation of the chromatin. Under certain conditions, of which a high temperature is one, though probably not the only one, spirochetes tend to reappear in the tick about ten days after feeding. This occurs suddenly, immense numbers being found in the tissues and cells of the body. These are at first different in appearance from the blood forms, being smaller, thinner, more faintly staining, and showing greater irregularity in their curves; they are actively motile. These young spirochetes have been frequently seen in stained films arising, apparently, from granules, and by the continuous observation of living specimens, at a suitable temperature, this origin has been confirmed. When once young spirochetes have made their appearance they tend to persist in this form throughout the life of the tick, and there is some reason to think that it is this form, or the granule stage immediately preceding it, which is most infective. It appears probable that the relapse in man and in animals may be due to the development of fresh crops of spirochetes out of granules formed by those organisms which caused the first attack. Observations upon other pathogenic spirochetes make it probable that a similar cycle of development is common to them all.

2. Optic Neuritis in Encephalitis Lethargica.—C. P. Symonds reports four cases of optic neuritis in encephalitis lethargica, discusses the diagnosis between it and optic neuritis in disseminated myelitis, and sum-

marizes as follows: 1. Four cases are reported in which optic neuritis was associated with signs of widespread lesions of the nervous system. 2. Despite individual points of resemblance none of these cases corresponds with the clinical picture of acute disseminated myelitis, anterior poliomyelitis, or acute febrile polyneuritis. 3. If the definition put forward by Barker, Cross, and Irwin be accepted, the clinical signs of all four cases are consistent with the diagnosis of encephalitis lethargica. 4. In Case 2 the Wassermann reaction in the blood was feebly positive. In the blood of Cases 1, 3, and 4, and in all four cerebrospinal fluids, Wassermann reaction was negative. 5. In all four cases the cerebrospinal fluid showed changes consistent with the diagnosis of encephalitis lethargica. 6. In the association of optic neuritis with acute disseminated myelitis we have an instance of involvement of the optic nerves in a diffuse inflammatory process affecting the nervous system, which is analogous to the association of optic neuritis with encephalitis lethargica.

5. The Danish Treatment of Scabies.—Svend Lomholt gives the details of a method of treatment of scabies which requires only one inunction, twenty-four hours after which the scabies is cured, and relapses are never seen. The ointment used, which was composed by Marcussen, is given as follows: (1) 1 kg. of sublimated sulphur is dissolved at a gentle heat in 2 g. of a 50 per cent. solution of potassium hydroxide. This makes a clear, yellow solution. (2) 225 g. of vaseline and 225 g. of water-free lanoline are carefully mixed, without heating. (3) To this mixture 375 g. of the solution of sulphur in potash-lye mentioned above is added. (4) Fresh zinc hydroxide is prepared by mixing 28 g. ZnSO₄ and 40 g. 20 per cent. sodium hydroxide, and this is afterwards added to the ointment. (5) Liquid paraffin is added to obtain a total of 1000 g. (6) 5 g. of benzaldehyde is added to check the somewhat disagreeable smell of sulphureted hydrogen. The high sulphides of potassium, he says, are the capital element of the ointment, upon which its activity depends, a production of sulphureted hydrogen taking place when the ointment is placed upon the skin. In making the inunction the patient first receives an ordinary cleansing bath, wipes himself thoroughly, and afterwards rubs the whole of his body, except the head, carefully with the ointment, which is almost of the consistency of butter. The ointment must cover all the skin, but hard rubbing is neither required nor desirable. The patient ought to wait for half an hour, to give the ointment time to get into the skin; after this he can go to bed. The next day at the same hour he receives a second bath and fresh underclothing, and the cure is finished.

5. Immediate Surgical Complications of Dysentery. Basil Hughes and Stanley Banks.

4. The Value of Extensive Inoculation of a Community During an Epidemic of Typhoid Fever.—Romanes and Johnstone record observations concerning compulsory inoculation, carried out by German doctors at six public centers, and also in private, during the winter of 1918-1919, shortly after the arrival of the British Army of Occupation in Germany. There were 199 cases of typhoid in the three epidemics in a town and villages of a combined population of about 20,000. Of these cases 34 died, approximately 17 per cent. Four of these deaths occurred in people who had been recently inoculated twice. The onset of the disease began within the first twenty-four hours after the second inoculation (two cases), on the eighth day after, and on the nineteenth day after the second dose. Two other deaths occurred in cases after the first inoculation, and in each case the symptoms began within the first twenty-four hours. There were altogether thirty-eight cases of typhoid following inoculation, and among them there were six deaths—that is, a mortality of 15.7

per cent. With the exception of these six deaths practically all these cases were of a light nature. The writers consider that it is hardly justifiable to arrive at any definite conclusion from these figures. The daily numbers of onset were very much on the decrease before the inoculation was begun, but some of the cases were not removed at once to the hospitals for isolation and were acting as sources of infection for some time afterward. During the early period of inoculation there were probably more sources of infection "at large" than appeared at first sight, and one would be inclined to imagine more people, as a result, incubating the disease. The fact that there was in each epidemic a recrudescence of cases immediately after inoculation tends to support this theory. Romanes and Johnstone hold that the arguments against inoculation during an epidemic do not appear to be supported by facts, and it is further claimed that additional evidence has been brought to light in favor of inoculation under these circumstances.

5. Immediate Surgical Complications of Dysentery.—Hughes and Banks give the immediate complications of dysentery as acute hepatitis; acute liver abscess; perforation of the colon (gangrenous colitis); gangrenous proctitis; synovitis with effusion into the larger joints. In case of doubt as to the diagnosis of acute hepatitis, it is justifiable to give the patient a course of emetine before undertaking any operation. If the condition be one of pure amebic hepatitis, improvement will show itself within three or four days, and the symptoms will soon subside. In acute liver abscess the treatment that gave the writers the best results was an anterior incision about two inches in length through the right rectus muscle. The liver was exposed and packed off with dry sterile gauze from the general peritoneal cavity. A long pair of sinus forceps was introduced into the right lobe in an upward and backward direction, and it was readily felt to enter the main abscess cavity. The contents were evacuated and a large tube was introduced. The patient was nursed in the sitting position. Into the abscess cavity, through the tube, quinine bichloride was introduced three times daily, the patient being lowered for half an hour to prevent its escape. In addition emetine (1 grain) was administered hypodermically daily for the first ten days. At first eusol was instilled through Carrel's tube placed inside the large drainage tube, but this was not successful, the liver being found post mortem to be acutely autolyzed. Out of nine cases operated on there were five recoveries and four deaths. In none of the cases did they employ the transpleural route for approaching and draining the abscess. Perforation of the colon (gangrenous colitis) was notoriously fatal. The writers never saw or heard of a case that recovered. The onset of the abdominal distension is so rapid that when once it has occurred operation seems hopeless. The toxemia is so intense that these patients die within a very short time, and operation only hastens their end. In gangrenous proctitis colotomy seems to be the only possible treatment. From their experience, however, the patients are too ill to stand any surgical interference. In synovitis with effusion into the larger joints, by far the most satisfactory treatment is early aspiration of the contents and the injection of 5 c.c. of ether into the joint cavity during the acute stage. A general anesthetic is usually required.

3. The Influence of Protein Food on Increased Blood-Pressure.—Herman O. Mosenthal records blood-pressure determinations made on patients who had been in bed for several days. This allowed the arterial tension to assume the lower level which mental and physical relaxation bring about. The manometer readings were made at approximately the same time every day. The patients were kept in bed continuously during this study. The long period over which some of the observations were carried out serves as a control for the fluctuations that may occur in the level of blood-pressure of individuals suffering from hypertension. During the periods of low-protein feeding the diets did not contain meat, meat products (such as soups or gravies), or fish. These foods were taken in considerable amounts on the days of high protein feeding. From these observations, which are tabulated, it would appear that it is exceptional for a low protein diet to diminish the blood-pressure or a high protein diet to raise it. One case, however (Case 9), shows that this may occur. This patient was extremely ill, as the great impairment of renal function indicates, and was necessarily maintained in a state of undernutrition, since any attempts to increase the food resulted in uremic symptoms. However, even in this case a second period of low protein feeding failed to bring the blood-pressure to the low level previously obtained. The diminution of the waste products in the blood, as indicated by a lowering of the blood urea nitrogen, was without effect upon the blood-pressure. Changes in the caloric value of the diet, for a short time at least, did not influence the blood-pressure. The demonstration by Benedict and his collaborators that by underfeeding the blood-pressure of healthy young male adults could be distinctly reduced, and that this change was accompanied by various other phenomena, among them a secondary anemia, furnishes a suggestion as to the therapeutic application of diet to hypertension. A subcaloric mixed diet may be continued for a considerable period, probably with beneficial effect. If the health and strength of the patient are to be maintained it is advisable to regulate the amount of the diet according to the hemoglobin content of the blood. The hemoglobin percentage should not fall below 85 per cent. In most instances in the writer's observations a low protein diet continued for a period of a few weeks is without effect upon the blood-pressure.

7. Ileal Regurgitation, Nerves, and Diet in the Chronic Intestinal Invalid.—John Bryant gives the results of the nonsurgical treatment in a consecutive series of fifty chronic intestinal invalids as follows: No improvement, 6 per cent.; improvement, 8 per cent.; improvement plus, 86 per cent.; total improved, 94 per cent. On the basis of these results Bryant considers it justifiable to tell the chronic intestinal invalid that he has a better than 90 per cent. prospect of improvement and a better than 80 per cent. prospect of being very much improved as a result of a few months of nonsurgical treatment. This applies to the cases in which ileal regurgitation is proved. For the chronic intestinal invalid without ileal regurgitation progress should be proportionately more certain and more rapid.

10. The Contents of the Stomach: Its Study and Interpretation.—Elbridge J. Best outlines a method for the fractional stomach examination which makes it possible to complete all the tried tests of gastric study in two hours and gives connected pictures of the secretion during this period. The procedure is simple and can be carried out by any practitioner with the aid of his nurse. The gastric curves are placed in five groups, no stress being laid on the actual acid figures, but emphasis is placed upon the position of the apex and the two-hour level of the curves, the difference between the free and total acid curves and the behavior of the free HCl curve. By repeating an examination a more stable, reliable curve is obtained. By carefully following out the procedure given it is possible to become more intimately acquainted with the detail of gastric activity, thus making it possible to carry out treatment by diet and medication in a more intelligent manner.

Book Reviews.

WIENER ARCHIV FÜR INNERE MEDIZIN. Geleitet von W. FALTA und K. F. WENCKEBACH. 1 Band. 1 & 2 Heft. Vienna and Berlin: Urban & Schwarzenberg, 1920.

THE war had a powerful influence upon medicine as it had upon every other branch of human activity. One of the effects upon the medical profession was to increase tremendously the percentage of those men who are "specializing." It was a frequent happening that a medical officer was detailed to one particular line of work and becoming proficient in it he often continued it into his civil practice. Physicians were roused from the isolated devotion to far country practices and thrust into an existence rushing along under high pressure where he who failed to measure up to the opportunity soon was lost. In consequence there has appeared since the war a host of new journals devoted either to the comparatively narrow field of some specialty or to the scientific aspect of a broader but still somewhat restricted branch of medical work. This journal is one of the latter group. Fathered by the Vienna school of medicine it aims to publish the scientific accomplishments of Austrian workers in the field of internal medicine. It will contain purely clinical studies and such experimental investigations as apply to clinical problems or are of undoubted significance for internal medicine. Among the contributors to the first two numbers are Wenckebach, Eppinger, Economo and Kaufmann, so that it can be seen the journal starts out with a high grade of material. The Editorial Board represents ably the leading men in Austrian medicine and it is reasonable to expect that the articles found acceptable by them will generally be worthy of study.

THE FUNDAMENTALS OF HUMAN ANATOMY. Including its Borderland Districts. From the Viewpoint of a Practitioner. By MARSH PITZMAN, A.B., M.D., Professor of Anatomy in the Dental Department of Washington University, St. Louis. With one hundred and one illustrations. St. Louis: C. V. Mosby Company, 1920.

THE author of this work, in the preface, touches on the weak points of most of the modern text-books on Anatomy. With much of what he says on this subject we are in thorough agreement. But when we come to his own treatment of the matter, we must confess that we are disappointed. It is hard, in the first place, to see for what class of readers this book is intended. It contains snatches of anatomy, bits of histology, scraps of embryology, fragments of surgical or applied anatomy; and yet, in spite of the title, it contains less anatomy than any of the compends,—less even than some of the books written for nurses. In the next place, the book is poorly balanced; for example, more space is given to the development of the kidneys than to the description of either the humerus or the femur; the cerebrospinal fluid is treated at greater length than the small intestines; the clitoris and the penis, each, occupies more space than the hip joint; the description of hermaphroditism occupies more space than the description of the temporomandibular joint. The references to surgery imply a much greater knowledge of anatomy than can be gained from this book. Some of the descriptions are far from clear, for example:—"The pancreas is divided for descriptive purposes into a head, a hook process or neck, a body and tail, averaging roughly one-quarter times one times six inches in diameters." The illustrations are useful, and the book is well printed.

PRACTICAL VACCINE TREATMENT. For the General Practitioner. By R. W. ALLEN, M.A., M.D., B.S., Late Capt. N.Z.M.C. Paul B. Hoeber: New York, 1920.

VACCINE therapy has suffered at the hands of both its incredulous opponents and its overcredulous friends. The result is that at the present time it is either not given or else used in a routine perfunctory manner, often, it must be confessed, because the giver is ignorant of the proper method of administration. Allen emphasizes four points of importance in successful vaccine treatment. The proper organisms must be selected. The proper surgical treatment must have been carried out. The doses must be large enough and

it is very desirable to produce distinct though mild reactions. He is obviously an enthusiast but no less obviously not an unthinking one. He has some curious ideas as to the etiology of pneumonia and he does not approve of American-made vaccines. Some of the claims he makes as to the results he has obtained are so extreme as naturally to excite some suspicion. Nevertheless he recognizes some of the limitations of the treatment and it must be admitted that in his hands vaccines are given with a care and close supervision that is rarely approximated by the average physician. Under the circumstances it ill behooves us to criticize the results he claims to have achieved. The book is a stimulating one and will well repay a critical reading.

THE INDUSTRIAL CLINIC. A Handbook dealing with Health in Work. By several writers. Edited by EDGAR L. COLLIS, M.D. Oxon, M.R.C.P. Talbot Professor of Preventive Medicine in the University of Wales. (Late Director of Welfare and Health, Ministry of Munitions, and H. M. Medical Inspector of Factories). Modern Clinic Manuals. New York: William Wood and Company, 1920.

THIS little volume is likely to prove very useful to all who are interested in Industrial Medicine. The health, and hygienic conditions surrounding the workers are here given the attention which they merit. The chief topics discussed are:—The medical examination of the worker, choosing the worker, industrial efficiency and fatigue, hygiene and working conditions, the hygiene of the individual, food values in relation to occupation, food at the works, the ambulance room, and industrial employment of women. The chapters are all quite short, but contain much information, and are evidently written by physicians with special experience in this line of work. This book will prove of value to most physicians, and it would be a useful addition to the reference library of all who are in any way interested in the employment of many workers.

A TEXT-BOOK OF ORGANIC CHEMISTRY. For Students of Medicine and Biology. By E. V. MCCOLLUM, Ph.D., Professor of Chemical Hygiene, School of Hygiene and Public Health, Johns Hopkins University. Second Edition Revised. New York: The Macmillan Company, 1920.

THIS book was noticed on the appearance of the first edition. The present edition contains an introductory chapter on the purification and analysis of organic substances, and a concluding chapter of some forty pages on proteins. These two chapters add to the value of the book. Students looking for a small and attractive work will find this a useful introduction to an important subject.

EPIDEMIC ENCEPHALITIS (Encephalitis Lethargica). By FREDERICK TILNEY, M.C., Ph.D., Professor of Neurology, Columbia University; Attending Neurologist, the Presbyterian Hospital and the New York Neurological Institute; Consulting Neurologist, Roosevelt Hospital, New York; and HUBERT S. HOWE, A.M., M.D., Instructor in Neurology, Columbia University; Assistant Visiting Neurologist, the Presbyterian Hospital, New York. New York: Paul B. Hoeber, 1920.

IT would be difficult to imagine a much more effective presentation of the subject than is found in this book. The authors have devoted about one-third of their space to a review of the present knowledge of sleeping-sickness; in this section the tentative clinical types are discussed with free illustrations from cases and a résumé of the symptomatology, diagnosis, prognosis and treatment is included. In the other two-thirds are found eleven instructive cases, reported at much length, the neurological reports being especially good. A bibliography is appended.

This book is a notable illustration of the present tendency towards the case-history method of presenting a subject, which is especially valuable in neurology and psychiatry, as it is also in any subject which is comparatively new to the profession for one reason or another. Dr. Tilney and Dr. Howe have judiciously admixed their didactic parts with their illustrations so that the whole gives the impression of a clinic of excellent cases, well presented and illuminatingly explained.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Anniversary Meeting, Held November 18, 1920.

THE PRESIDENT, DR. GEORGE DAVID STEWART IN THE CHAIR.

DR. GEORGE DAVID STEWART, in introducing the speaker of the evening, said that in his farewell address the Father of his Country urged his people to indulge in such habits of thinking as might inspire caution in those entrusted with the conduct of the Government to the end that there might be no encroachment of one department on the domain of another; that was no consolidation of the various branches. For this usurpation he said was the customary weapon by which free governments were destroyed. Could he today revisit the glimpses of the moon, he would find I fear the habit of straight thinking sadly neglected for the most part by both the governments and governed. Still there were heartening exceptions, one of these exceptions was the speaker of this evening. A man of trained mind, who had devoted himself to the study of history, of politics and economics and who, regardless of self interest, contemptuous of party, mindful only of principles, had made strenuous efforts to have the people understand the moral and spiritual significance of their form of government as planned by the exceptionally able men—and there were giants in those days—who framed the American Constitution. His analysis and interpretation of that instrument was the finest with which we were acquainted. Of the Constitution he said, it was something more than a written formula of Government: it was a great spirit, the most quickening that now existed in the world. It was the highest assertion and indeed vindication of the morality of government that the science of politics had yet given to the world. Underlying its formal provisions was a profound moral philosophy and it was this fact that gave to its perpetuity a deep ethical significance. So illuminating was his analysis, and so reassuring his interpretations in this time of trial that Dr. Stewart said he wished every one could be familiar with his writings; for then might the wish of the founder of this great Nation be fulfilled. This was the Anniversary Lecture. Our founders realized that man could not live by bread alone, that medicine touched all the sciences, all the humanities, and so it was provided that the Anniversary Lecture be not at all or only remotely related to medicine. He took great pleasure then in introducing Mr. James M. Beck, of the New York Bar, who would speak on "One Cause of the World Neurosis."

One Cause of the World Neuroses.—MR. JAMES M. BECK of the New York bar delivered this address which he prefaced with an apology for having come before the audience without having prepared an address in a literary form such as the intelligence of the members of the New York Academy of Medicine and the dignity of the occasion required. He said, in part, that he had not come to demonstrate a thesis, but simply to suggest a thought that might be new and which he trusted would be found deserving of further thought and consideration, and which might be the subject of speculation that would lead to conclusions far more definite and valuable than any he might suggest tonight. The subject he had selected, "One Cause of the World Neuroses," might perhaps have been stated as "One Unsuspected Cause of the World Neuroses" for it was one to which he had heard very few refer. To establish his premises, since some might ask him to establish the fact that there was a world neurosis, he would quote from an address delivered before the New York Academy of Medicine on October 16, 1919, by an eminent Princeton Professor, Dr. Stewart Paton, who said "A great deal of the present emotional unrest seems to be due to two causes: On the one side there has been an exaggeration of the previously existing and well recognized types of emotional instability, and on the other a definite psychosis with certain specific symptoms and markedly epidemic tendencies, affecting persons possessing intellectual ability, has become a menace to

civilization. The effects of this disorder have already imperilled the permanence of many human institutions, have made the establishment of conditions essential to the restoration of peace increasingly difficult, and have jeopardized the rational control of behavior which men acquire only after ages of toil and painful experiences." (MEDICAL RECORD, Nov. 15, 1919.) Dr. Paton then enumerated a few characteristics which had come to be accepted as indicating the presence of a sound mind in a sound body. These signs were subjectively: (1) "Joy in living." (2) Pleasure in work. (3) No desire "to varnish the fair face of truth with the pestilent cosmetic of rhetoric." (4) Temperance in wishful thinking. (5) No apologies for self-insufficiency. The objective signs of sanity as given by Dr. Paton were: (1) Prompt action in emergencies. (2) Behavior controlled by normal and not supernormal idealism. It was to the first of these two evidences of a normal state as opposed to psychoses to which Mr. Beck particularly drew attention—joy in living and pleasure in work, and a sense of adequacy and self-sufficiency which was the greatest and least appreciated of all man's possessions. Dr. Paton went on to say "Remember that the muscular system, which is millions of years older than the nervous system, gives the 'set' to all our activities, and to a very large extent determines our attitude in general toward our environment." While the psychoses from which the world was suffering could have many symptomatic indications, it was the lessening joy and satisfaction in work that was most marked in man today. It was a matter of experience that within reasonable limits the more a man worked the more he wanted to work, and the more a man worked the more he enjoyed work and the better was he able to work, and on the contrary, the less a man worked, the less he liked to work and the less able was he to perform work. All over the world today, notwithstanding higher wages, shorter working hours, all manner of machinery to lighten toil, and a higher degree of comfort and luxury than man had ever known before, there was a lessening efficiency, a lessening ambition, and a lessening ability. If there was an instability marked by a lessened desire to work, what was the cause? Before answering this question, Mr. Beck said he wished to use an analogy drawn from a source from which he liked to draw illustrations. One of the most profound metaphysicians whose works had come down to us, though he never laid claim to preeminence in that domain was Shakespeare. His characters were fashioned from marvellous insight into the human mind. He selected a particular trait or emotion and then fashioned all the characters and circumstances of the play to bring out this particular characteristic. In Othello it was jealousy; in Macbeth ambition. In Hamlet, the young Prince of Denmark, Shakespeare drew the picture of a man most superbly endowed by Nature, a man of wonderfully perfect physical form who could best be described in Shakespeare's own words,

"The courtier's, scholar's, soldier's eye, tongue, sword;
The expectancy and the rose of the fair state,
The glass of fashion and the mould of form,
The observed of all observers."

and again, in the words Hamlet used in speaking of his father,

"A combination and a form indeed,
Where every god does seem to set his seal,
To give the world assurance of a man."

These words fittingly described the favorite child of the poet's fancy. But we found this man beloved of the multitude, with all the advantages of birth and culture, never compelled to act, reading, philosophizing, soliloquizing, but never acting. We found him forever putting off the duty of the hour. Hamlet himself left us in little doubt as to the cause, which he indicated in the following lines.

"And thus the native hue of resolution
Is sicklied o'er with the pale cast of thought
And enterprises of great pith and moment
With this regard their currents turned away
And lose the name of action."

There were in the play two very significant intimations to account for Hamlet's lack of will: He said, "I have of late—but wherefore I know not—lost all my mirth, foregone all custom of exercise." Reading further we find that by reason of the destruction of the nice equilibrium between physical action and mental activity the whole world had become clouded. "This godly frame, the earth, seems a sterile promontory. This most excellent canopy, the air, look you, this brave overhanging firmament, this majestic roof fretted with golden fire, why it appears no other thing to me than a foul and pestilent congregation of vapours." With less poetic touch his mother said, "He's fat and scant of breath." Commentators had rebelled at that and had substituted "faint" for "fat," but Shakespeare meant what he said, Hamlet was fat and scant of breath. He had been brought up as a prince of royal blood with no necessity for action and no incentive for action; he was lost in his books. The life at Wittenberg was having its results, it was destroying the equilibrium between mental and moral and physical activities, by excessive meditation and denial of action to his physical powers. Samuel Taylor Coleridge said, "Action is the chief thing in existence. No faculty of the intellect can be considered valuable, or otherwise than as a misfortune, if it renders us repugnant to action."

After going still further into an analysis of Hamlet's character, Mr. Beck said that the practical thing that we got from this analogy was the necessity of a just equilibrium between the outer world and the intellectual processes, and that failure to maintain this equilibrium was at the peril of psychosis. The first essential to a healthy mental state was joy in work. If we could get at the root of the satisfaction that man got in work we might then find what was causing the present unrest that was shaking the foundations of governments, and even of our own government. He believed that one cause of the present world neuroses was the lessening satisfaction in work, which was the legitimate development, and it was to be hoped the culmination, of a profound revolution—a revolution not caused by the great war—though its evils were profoundly exaggerated thereby. The fact that the world war gave opportunity for a demonstration of physical and moral power the like of which we had no record or parallel, did not in any way militate against his theory of psychoses, for even lazy men were known to arouse themselves and to exert unusual energy when actuated by the instinct of self-preservation. Even Hamlet in the final act had aroused himself to activity, so the fact that the nations of the world gave a demonstration of physical and intellectual power when their existence was threatened in no way affected the conclusion that there was today a malady in the human soul that was poisoning human life. That malady was the lessening joy and satisfaction in work and it marked millions of men. It was the result of a revolution which had been going on for one hundred and twenty years. Mr. Beck then went on to show that in the history of the evolution there was nothing to show that man had changed physically in 500,000 years, or if there had been a change it was in the direction of weakness rather than strength. During all the centuries preceding the Nineteenth of which we had record, man had lived under an agricultural system. During all those centuries man had sowed and reaped in practically the same way, and had traveled in the same way. In the last one hundred and twenty years, since the invention of the steam engine, man's methods had been revolutionized. While man physically had not advanced a particle, that is to say as a specimen of a genus, during 500,000 years, yet in the brief space of one century, through the powers of his mind, he had passed from the state in which he had existed for centuries to the state of superman. These changes, so stupendous that they staggered the imagination, had been brought about largely in two ways. The first of these was the recognition of the value of concerted action, the realization of the fact that by association with others man could increase his powers of achievement and extend them over a period far beyond his allotted three score and ten years. Then too the strength of an association was not only as great as the aggregate strength of those composing

the organization, but this strength was intensified by the aggregation and acquired a progressively increasing power which under certain circumstances became a menace we could not afford to ignore. As to the second and greater conception, this was that man could annex to himself the powers of Nature. He could add to himself what Samuel Butler termed the *extra corporum*. To illustrate, when man took hold of the handle of a hoe the hand grasping the handle of the hoe became a new elbow, and the hoe blade became a new hand, and the man thus acquired a new hand that could do things that he could not do without it. In other words, the hoe became an *extra corporum* annex. This principle was applied on a more stupendous plan when a man annexed an aeroplane. Man had by annexing the aeroplane become not only a superman but a superbird. This had been expressed by a French aviator recently, who, after performing maneuvers in the air, when he came to a standstill said "The birds do not know how to fly because no bird can fly upside down as I have done." Among other extra corporeal additions were the submarine and the telephone. While we had been slow to appreciate the fact by these extra corporeal additions we had become supermen, and we could truthfully say with Hamlet "What a piece of work is man! how noble in reason! how infinite in faculty! in form and moving how express and admirable! in action how like an angel!" That was all true, but fully conceding these wonderful changes wrought by machinery that had made of us supermen and had enabled us to build up great and over-populated civilizations, what had that done for the human soul? What had been the effect of one hundred and twenty years of development of machinery on the human soul? Mr. Beck quoted from Samuel Butler's *Hudibras* in which he described how man, at first the master, slowly became the slave of the machine, and asked the question "May it not be that man is becoming a sort of parasite on the machine?" Man had come to depend upon machinery to such an extent that if it were all destroyed he would perish and the race would become extinct within three months. Butler went on to say "May it not be that the machine is gaining ground and becoming more and more human? If it has taken millions of years to evolve man from primordial protoplasm, who can say that in the course of millions of years, machinery may not evolve consciousness and exact mastery over man?" Of course this was unthinkable, yet it would be no more wonderful than man's evolution from primordial protoplasm. One of the effects of machinery was laziness. Machinery had destroyed man's incentive to industry, his pride in creative work and his joy in achievement. It had destroyed his ability to work by lessening the need of what was really work. When one spoke of work as action in the sense in which Coleridge spoke of it, he did not mean the kind of employment which was so general today. The man who sat by a ticket chopper and watched others drop in tickets simply idled; he was not working. The man in the subway who guided a motor through a marvellous perfection of machinery and watched the track was employed in a way but he was not doing real manual work. And so it was through all the industries, one scarcely found such a thing as work in the sense of an active effect upon the muscular system. The muscular system was older than the nervous system. If the muscular system was starved one could not have a healthy well-rounded life. Before the invention of machinery man took a pride in his craftsmanship. The cobbler who made a shoe himself took a pride in turning out a perfect piece of workmanship, but the man who stood at a factory bench and watched a machine punch eyelets—perhaps so many thousand per minute—a machine which never made a false move, never stopped a moment, never dropped a stitch—the man who watched such a machine day after day, and week after week, went through a process of boredom that left no wonder that there should be this profound unrest. Increasingly the necessity for work and the incentive to work was being destroyed. At the moment it seemed that man was losing the mastery, leaving all to the machine and becoming the slave of the machine. With this state of affairs we could not but expect the gravest psychological disturbances. Men were taking a less active

part in sports than they formerly did. Men might go to a baseball game to look on, but there was less ball played today than a generation ago. Another form of amusement that typified the laziness of the present day was the "movies" as they were called in the common vernacular. The movie was the final consummation of laziness born of machinery. The movie gave the maximum of emotion with the minimum of mental effort. It was merely looking at pictures—a way of passing time that gave a vivid impression and saved mental effort. A mental and moral psychosis of laziness was at the root of social disorders today and was due to causes which could not be controlled because we had taken from man his opportunity and his incentive to work.

Sir Alfred Geddes had said the next fifty years would be either the most constructive or the most destructive fifty years the world had yet seen. We could make it the most glorious fifty years in human history if we kept before us the three ideals of beauty, service, and truth. Mr. Beck then discussed the effect of machinery on these three ideals. Taking up beauty he took the theater as an illustration, since here we had beauty of thought, beauty of sound, and beauty of scene. Today in New York City there were over fifty theaters, and there went through the box offices of these theaters in 1919 some \$100,000,000, and through the box offices of the theaters of this country \$800,000,000. The theaters never before had such patronage, or so many accessories. The theaters of Shakespeare's time were tawdry things by comparison with those of today, yet the theater was never less productive of works of intellectual and moral beauty. The function of the theater was to amuse, to instruct and to inspire, but today Aristophanes had degenerated into George Cohan and the two Romeos into Mutt and Jeff. There was not only a lack of art but a debasement of wit. As to the power of the theater to instruct, that characteristic of the theater did not exist today. The Greeks held their theater as a shrine and a temple, and a play as a solemn ceremonial which served to inspire. Greece, with a population less than the State of Rhode Island, gave to the world in the brief space of two centuries twenty-five of the supremely great men of all history. It gave a Euripides, a Sophocles, a Socrates, a Plato, an Aristotle. Surely we must acknowledge that machinery has had a deadening effect on beauty. As for the idea of service, there was never a time when the love of service for service's sake was as low as it was today. We had gone far from the idea of service expressed by Orlando, when his old servant begged to accompany him and asked for no wages,

"O, good old man, how well in this appears

The constant service of the antique world

When service sweat for duty not for meed,

Thou art not the fashion of these days."

Millions today regarded work as servitude. The means for supplying the external necessities for a joyous life were never so great, there were never so many devices for making work less arduous, and education was at a higher level than ever before, yet man was less disposed to work than he ever was. The higher the wages the less efficient the work; the fewer the hours of work the less the efficiency and the greater the number of strikes. False trades unionism involved this syllogism: From the time machinery started to be instituted the trades unions taught that the less work men did the more remained to be done, and the greater the demand for labor; the greater the demand for labor the greater the wages, therefore they would not work. That principle was adopted and men did as little work as possible and did it as dishonestly as possible. This principle was not based on sound political economy. One could not lift himself by his bootstraps. This policy inflated values and diminished the value of wages. Machinery by giving *extra corporum* aids to man had enabled him to become greater than man, he had become superman in respect to his control over physical forces. But instead of it making him a greater man morally and spiritually, he had deteriorated in moral fiber, so that he no longer cared for the greatest and noblest thing in life—work. Work was the greatest and noblest thing in life, for without work life was not worth living. Man no longer recog-

nized this truth. A debasing and degrading philosophy, not sporadic and local but almost universal, gloried in minimizing the value of work. That philosophy was one of the effects of machinery, but it was also caused by machinery gradually becoming the master of man. One might recall the fable of Prometheus, who stole the fire from Heaven and was bound to Mount Ida with the vultures preying on his vitals. Man stole the fire from Heaven when he invented machinery and he was now chained to the machine, and the vultures of hatred, insubordination and selfishness were preying on the vitals of all classes.

Mr. Beck then proceeded to note the effect of machinery on the institutions of the family, the Church and the State. He declared that there was no one who claimed that family life was now what it was one hundred years ago. There was a disintegration of that fine loyalty in the family that we formerly knew; and indeed was not the function of the family marked by its abandonment? The Church, no one Church, but the Church as a whole, had lost its hold. Men no longer seemed to feel the need of assembling themselves, as was formerly the custom, to pray to the Great Unseen. Was it not that "The Voice of the Ages" was drowned out by the voice of machinery? One thing Mr. Beck said he had studied all his life, that was the State, and there never was a time when the authority of the State was mocked and flouted as it was today. Human authority was in the process of disintegration. Just as a globule of mercury coalesced and then separated, there was a shifting of power from the State to so-called self-governing groups. This power of association was acting here, and human society through association was destroying individuality; the individual was submerged and became a part of the group and much of his independence as an individual was gone. As an example of this we had organized labor controlled by a few men in Washington. They told a man he could not work unless he had a card and paid for the right to work. They took their group power and used it to blackmail. The robber barons along the Rhine, in medieval times, played fair and conducted a respectable business compared with what we saw today. Using group associations, they said you should not work to support your wife and children unless you paid so much. Then they turned around to the the employers of labor and said "You give us so much or we will call a strike and paralyze your industry or your transportation." All the functions of life were slowly disintegrating into semi-autonomous groups, and all were more or less subject to the power of the group. These groups had grown so powerful that they could say to the State "You do our bidding." It might be recalled that the labor group with stop watches in their hands said to the government, "You sign this statute defining wages or we will paralyze transportation and starve every community dependent upon transportation for the necessities of life." The President and both political parties yielded. Last summer when the Bolsheviks were at the gates of Warsaw and the British Government, fearing that if Lenin and Trotsky dictated terms the civilization of Western Europe would be imperilled, wished to send aid to Poland, the labor group said "You do so and so, or we will cut off the supplies of life." And the British Government yielded. Group association and the power of machinery were dictating to the State and when that form of insubordination was reached the foundations of the State were being menaced. By standardizing men we had destroyed their individuality, and there was no greater element or source of progress than that originating with the individual. The thing that made Greece so great was the free and open expression of individuality. Today everything was fashioned in a common mould and stamped with the dead level of mediocrity.

One other aspect, the ability to see truth clearly—Never was there a time in the history of the world when there was so much muddy thinking. Before the age of machinery man knew but a few things, but he knew them well. He did not try to make his brain a garret as we did by incessant and universal reading. Washington could not talk through a telephone or dictate to a stenographer, but he could write things that will outlive what is written today with the aid of our

modern devices. It took Alexander Hamilton a much longer time to go to Washington than it did us today, but did we go to better advantage? Take the Constitutional Convention, the men who framed that instrument met for four months and worked out a Constitution of 4,000 words, 109 sentences, yet a masterly piece of statecraft, which was not only the admiration of all, but was taken as a pattern by other nations when they had undertaken to draw up an instrument of government. Compare the Constitution with the work of the Peace Conference, a document of 80,000 words, yet no one could claim that it had achieved clarity of thought; on the contrary it was thick with the muddy complexity of the thought of today. Today words were substituted for thought. Words were absolutely without end. We were suffering from a disposition to utter words without any clearly defined or precise idea of their meaning. Why was it? It was because there was such an infinite complexity of thought. We tried to know too many things without knowing how to use our knowledge. There was a vast difference between knowledge and the ability to use it. Machinery had diversified life and added to its complexity but it had not added any new conception of truth. We might know more along certain special lines, but so far as the general philosophy of life was concerned it was doubtful if we knew as clearly as our fathers knew. They had the power to translate thought into effective action, because they recognized that there could be no effectiveness of thought without action; that without action all thought was superfluous.

Mr. Beck stated that he had preferred an indictment against machinery, but he could not dispute that the man who invented machinery was one of the greatest benefactors of humanity. We could not conduct the affairs of life today without machinery. He had only suggested that the effect of machinery on the human mind and soul was in part prejudicial, and it was in his judgment entirely clear that this was one of the causes of the world psychoses. He doubted not someone would say "Well, what is the remedy?" He disliked that question and considered it unreasonable. The fact that he had no remedy to propose did not affect the soundness his remarks might otherwise have. He would, however, suggest the thought that we should more and more counteract the influence of machinery on man's mind and spirit. We must revolutionize in the mind of the manual toiler his whole political philosophy, for so long as he persisted in his present idea of trades-unionism he was not impressed with the dignity and nobility of labor. He must learn that the dignity of labor consisted in doing much, not little. He must become interested in the machine and must find in it a way of giving play to craftsmanship. There must be found a way to give play to muscular activity and to mental effort. We must bring to the attention of every man the necessity of not allowing mechanical appliances, which were extracorporeal additions to man's physical powers, to destroy the equilibrium between his physical nature which found its chief satisfaction in work, and his moral and intellectual nature, which also found its greatest satisfaction in work. We must teach not only the dignity of work, but the holiness of work. Humboldt, years ago, wrote an interesting thing in reference to the etymology of the word America, something which should be taught in the schools and which would help to counteract the debasing effect of machinery. If asked what America meant, the reply usually was that it was named for Amerigo Vespucci, who discovered the continent. According to Humboldt, Amerigo was an Italian corruption of two Gothic words, "amal," to work, and "ric," to conquer. Amalric in Italian, America in English, meant the work that conquered—all conquering work. It was all conquering work that made of us a great nation. In all other days men worked with energy, pride, and joy. All conquering work was good American doctrine. All conquering work was the vital essence of human life.

Dr. M. ALLEN STARR voiced the profound appreciation of the members of the Academy and their guests of the very eloquent address to which they had listened and moved a rising vote of thanks to Mr. Beck, which was given unanimously.

SECTION ON PEDIATRICS.

Stated Meeting, Held November 11, 1920.

DR. CHARLES HENDEE SMITH in the Chair.

Fat Determination in the Feces.—DRS. ROWLAND G. FREEMAN, JR., and EDGAR G. MILLER, JR., presented this paper, in which they reviewed the earlier methods of fat determinations in feces, and described their methods. This consisted essentially in triturating the weighed moist feces with anhydrous sodium sulphate, extracting the resultant dry powder with ether, and weighing and fractionating the ether-soluble material by the usual means. Samples (from one to five grams) of the moist material were weighed out and triturated in a mortar with one to three c.c. of concentrated hydrochloric acid; after about five minutes the mass was triturated with anhydrous sodium sulphate until the whole presented a dry, finely divided powder. About 35 to 40 grams of the sulphate was required for a gram of feces, although this might vary. The material was then transferred quantitatively to a well stoppered Erlenmeyer flask, a quantity of pure ether (about 50 c.c.), free from non-volatile material, was added, and the mixture shaken for several minutes. After a brief time to allow for some settling the ether was decanted through filter paper. This extraction was repeated until no more ether-soluble material was obtained; usually four or five extractions were sufficient. The residue was then washed with a little more ether. The combined ether extracts were then evaporated in a weighed beaker to dryness, dried at 98–100° C., desiccated, and weighed. The weight of the extracted material represented the figure commonly known as total fat. Having the "total fats," these might then be dissolved in hot benzol and triturated while hot with N/10 alcoholic sodium hydroxide, using phenolphthalein as indicator. This gave the amount of free fatty acid. Fatty acids present as soaps might be determined by repeating the extraction on a sample which had not been treated with the hydrochloric acid, and recording the difference between this and the result of extraction of the solidified sample. Pure beef fat and pure stearic acid were recovered by this method to the extent of 99 per cent. The chief claim for this method was its speed and its availability for ordinary clinical testing. Its accuracy, while high, was probably exceeded by some of the longer and more complicated procedures.

Dr. ROWLAND G. FREEMAN said the clinical examination of the feces had been difficult and in many respects unsatisfactory. One of the great values of feces examination was in children with poor digestion, those children who were constipated, poorly nourished, and in a generally miserable condition, and in whom it was important to find out what element in the food was not being taken care of and passed in excess in the feces. The Schmidt test afforded a good method of obtaining this information so far as the proteins and carbohydrates was concerned, but not for the fats. The Sudan III method had been quite generally used in the estimation of fats, and the reports of his laboratory had stated that the fat content was so many droplets in a D field, but gave no idea of the size of the droplets or the thickness of the field, so that it was evident that a more accurate method was needed. In comparing this method with the Sudan III method he found that the Sudan III method was absolutely unreliable and misleading: 8 fat droplets were reported in feces containing from 19 to 29 per cent. fat; 10 droplets in feces containing from 30 to 32 per cent. fat; 11 droplets in feces containing 27 per cent. fat; 12 droplets in feces containing 28 to 41 per cent. fat. So whether this new method was adopted clinically or not it seemed to prove that the Sudan III method was unreliable and not worthy of use. The test described could be carried out so as not to take more than twenty minutes to half an hour per specimen, and was sufficiently accurate for clinical purposes.

Dr. GODFREY R. PISEK said they would all certainly be glad to have a new method that would throw more light on the stools of infants and children. The great trouble was to develop a method that coordinated laboratory and clinical findings. The difficulty in connection with the fats in the feces was that when they

sent a specimen to the laboratory the laboratory and the clinical view often did not coincide. For example, the examination of the feces might show that a large amount of fat was absorbed while clinically they had evidence that the child was not absorbing fat. We did not know to-day just what the significance of the fatty acids and soaps were, hence we would be grateful for anything practical along this line that would be helpful.

Dr. MILLER agreed that what Dr. Pisek had said in reference to the coordination of clinical results with laboratory findings was extremely important, and for that reason they hoped for series of cases from various hospitals in which this method was used. Several such investigations were now under way.

Anhydrous Dextrose in the Feeding of Bottle Babies.—Dr. WILLIAM H. PORTER read this paper, in which he said that physiologists had long known that there was only one form in which starch or sugar could enter the circulation, and that was glucose or dextrose. For this reason and the fact that dextrose was the most soluble of all forms of sugar, the author was led to believe that pure anhydrous dextrose could be quickly and fully absorbed into the circulatory system and utilized by infants when no other form of sugar—not excluding the maternal milk sugar—could be so utilized. For dextrose could undoubtedly be appropriated by the infant economy to produce the heat and energy necessary to innervate the digestive functions, especially during the first day or two of the child's life, when it was so difficult to get the baby's digestive apparatus into a state of functioning activity. The particular product used in this investigation was an anhydrous dextrose, the anatomical construction of which was such that it was much more quickly reduced than any of the other dextrose. They believed this was still another and peculiar isomeric form of dextrose more closely approximating that particular form developed by the physiological transformation of mothers' milk in the human economy than any other isomer of glucose. The reason for believing that this was a special glucose form was further manifested in the clinical results which followed the administration of this particular glucose. The results were not comparable in any degree with those attained by giving dextrose derivatives produced by malting, or developed from grains other than corn. The product under consideration was a chemically pure dextrose, a dextrorotary sugar furnished for these researches through the courtesy of the Corn Products Refining Company. Collaborating in the study were a number of the leading pediatricians and other specialists of New York. The combined number of cases treated by these physicians totaled well over 140. Many of the babies included in the series were institutional babies, in desperate condition, and the observations were made during the summer and fall months, during which the infant mortality reached its most alarming proportions. However, the results of these researches went to prove that the babies did quite as well, and in many cases much better, on dextrose than on any other form of sugar. In cases in which there was diarrhea and green stools, with rapid emaciation, very large doses—2 to 4 ounces—of dextrose was tolerated. In from twelve to twenty-four, or forty-eight hours at most, the diarrhea was stopped, the stools became normal, and the baby was again in a thriving condition. This sugar in small amounts did not primarily inhibit sugar growing bacteria, but, when used in larger doses, it seemed to exert the preserving properties common to all saturated sugar solutions. In this was it inhibited the development of bacterial flora which had heretofore led pediatricians to temporarily discontinue the use of sugar in infant feeding. Also by the ability of dextrose to maintain heat production, the baby's digestive apparatus was stimulated to produce more hydrochloric acid, phosphate of soda and digestive ferments quickly. These secretions were immediately brought back in full amount and quality, thus producing the normal inhibitory agents which arrest pathogenic bacteria and microbial growth in the intestinal tract. The much dreaded primary sugar fermentation was stopped, the infant returned to health. Our first heat-producing food product, dextrose, had thus been turned into a powerful therapeutic agent. And if the results attained in this investigation were fully

maintained, it was quite possible to that 90 per cent. of the 40 per cent. of babies now condemned to die under the past régime would be saved. As a further aid in this inhibiting process it was well to remember that the addition of a little salt would augment very materially the production of hydrochloric acid. The anhydrous dextrose slipped directly into the blood without the expenditure of any digestive energy, augmented the combustion of fat, perfected the metabolism of proteins, especially in their oxidation reduction in some of the gastric cells, and thus stimulated the production of hydrochloric acid by nature's own method. This resulted in generally increased efficiency, and assisted in developing the digestive ferments produced by the liver, pancreas, and the various intestinal glands. With the improvement in these physiological activities, the endocrine glands performed their functions more normally. Hence a more perfect metabolism could be developed and maintained. It might also be mentioned that normal heat production was also essential to the excitation of nerve innervation—a factor which must never be lost sight of in dealing with sub-vital cases. From a summary of 103 bottle baby cases, submitted by the Board of Health and the various pediatricians mentioned in the paper, it seemed that fully 75 per cent. demonstrated a decided gain, there being a fairly uniform increase in weight. There were no complications in the way of vomiting or green stools that could be distinctly referable to the use of this particular sugar form, and in many instances babies who failed to gain on other sugars, when put upon dextrose, immediately commenced to increase in weight. Of the cases which were unfavorable or in which there was an indeterminate result, there was no single instance coming to the knowledge of the essayist in which any other sugar substituted for dextrose resulted in improving the clinical aspects of the particular case. While the pediatric observations were under way the author personally observed the action of the dextrose in some 35 adult cases varying from mild conditions of mal-metabolism up to cases in which death seemed inevitable. In every single instance a decided improvement was secured, many of the patients evidencing a most remarkable change for the better in metabolic and assimilative powers. In practically all of these cases a careful study of the urine was instituted in order to determine whether any of the dextrose came over into the urine, and also the effect of the sugar upon the excretion of albumin. In not a single instance did any glucose appear in the urine. The albumin was pretty uniformly reduced, and metabolism improved in every instance, even in one case which was most desperate. In one of these patients, with the exception of two in whom there was a decided disturbance in the digestion, and in whom absorption was temporarily arrested, was there any glucose found in the feces. In all the severe cases these results were verified by Professor Gies. Blood sugar tests were not made because the contention was that when the sugar tolerance had been exceeded glucose appeared in the urine. Their experience was to the effect that in anhydrous dextrose we had a therapeutic agent of proved merit, a stimulant which had won the merit of many of the leading surgeons of the world and a food product second to none in its carbohydrate value.

Dr. Porter, after reading his paper, said he had one diabetic patient for the last three months on this sugar and taking no other medicine, and there was no increased output of glucose either in the urine or feces, and no increased blood sugar. This patient was taking twenty-four teaspoonfuls daily in addition to the regular diet. He had used it in pneumonia for the purpose of heat stimulation with apparent benefit and had written a paper calling attention to that fact. One military surgeon had used it intravenously in 137 cases with uniformly good results. It seemed that large quantities of this particular kind of dextrose could be used without deleterious effect and with much benefit. He had given over 40 pounds during the last few months and felt that it was valuable both as a health-giving food and for therapeutic purposes.

Dr. HENRY KOPLIK stated that he had listened to the paper with a great deal of interest, but was not quite clear as to which class of patients this form of sugar was to be supplied. Pediatricians had been at great

pains scientifically to work out the underlying causes of the different forms of intestinal disturbances in infants and children so that when a child came under observation they would be able to tell what was going on with the baby and then proceed to remedy the cause of the disturbance. In other words, they had given up the idea that there was such a thing as a placebo, and from that point of view they had been working. The scientific man classified each condition in a rubric by itself or with conditions on the borderline in order that he might apply certain fundamental remedies suitable to that condition. How this form of sugar was brought forward and applied to almost everything. The fact that a baby had green movements and intestinal fermentation did not signify too much sugar unless the cause was known and then the condition might be brought under control. After the trouble was brought under control one then applied other forms of food, and in that way tried to recover the baby, so to speak. A baby might be disturbed by absolutely good food, food wholesome in every way, which in other babies was well borne, but in this baby was not well borne. A perfectly wholesome food might disagree with a baby and likewise a perfectly good sugar. Maltose, for instance, had been found very useful in some forms of intestinal disturbance, but it might be objectionable in others, but the reader of the paper did not say when we should use this form of sugar and when we should exclude it. We knew that in certain forms of intestinal disturbances cane sugar could be used and acted well. There was no particular thing which fitted every case. One had to classify conditions and ask himself what was going on in this particular baby, whether the disturbance was due to sugar, to fat or to protein and whether the baby was getting too much of any of these substances. It was true that certain forms of sugar were absorbed much more readily than others. For instance, Liebig pointed out that malt sugar was easily absorbed and well borne, and we had a form of feeding containing a large percentage of maltose, malt soup feeding. In other words, he would like to know more definitely in what class of infants this sugar should be used as an almost exclusive article of food in these very sick babies. This was not pointed out in the paper.

Dr. GODFREY R. PISEK expressed the hope that he would always be broad-minded enough to receive any new therapeutic or dietetic produce presented for trial; one could not afford to do less than that and be scientific. One must, however, also take the opposite stand and in these cases be prepared to be very conservative in his opinion and not allow any overenthusiasm in regard to any type of preparation to sway him. When this form of sugar was presented to him he thought it might possibly fit into a niche, since other forms of sugar had been found suitable to a particular condition, and if this were true we should like to know it. It was presented at a time just before the summer months to give it a fair trial in even a limited number of cases. At that time he stated that he would not be ready to go on record until this preparation had been tried by others, not only in this city, but in other parts of the country. Dr. Porter did not state and did not mean that he had discovered a panacea. He had just presented it in this way in order that a greater number might know something about it.

Dr. ROGER H. DENNETT said that since his name had appeared as concerned in this investigation he felt called upon to say a word in discussion. As he understood it certain amounts of this new sugar had been distributed among various hospitals, and at his summer service they had received their quota. He believed all pediatricists were supposed to receive a certain share. For three or four years he had been rather enthusiastic about the theory of monosaccharides. It always seemed to him theoretically that monosaccharides used in a certain type of baby not having good tolerance for sugar was a rational procedure, for the monosaccharides were easily absorbed and absorbed high up in the digestive tract. Thus it might be that they could be used without the bad influence that took place when sugars were absorbed lower down in the intestinal canal. Consequently he was very glad to try out this new sugar in a limited way this summer. In a very small number of cases in which he had used he could draw no definite conclusions. It seemed to

him that it would have to be used very extensively by a large number of observers before any very definite conclusions could be drawn by anybody.

Dr. MARSHALL C. PEASE said he hoped he had misunderstood the speaker, but he had the impression that he said that this was a type of sugar in which bacteria would not grow and particularly putrefactive organisms. He happened to know that bacteria would grow in any sugar that would be digested in the animal digestive tract, and that they grew most profusely in maltose and dextrose, and that they would grow though only a small amount of protein was present. But one strange fact was that they produced only a small amount of toxin in the presence of large amounts of sugar. The condition under which they produced toxin was slow growth in protein media and one having a slightly alkaline reaction, preferably 0.5 to 1 per cent. On the other hand, if they grew in a sugar medium of any type after a short time there was an increase in the amount of acid, and as the acid increased one found a smaller and smaller number of bacteria. The bacteria either died or were transferred into spore form. While this process was going on the bacteria were not producing much toxin. If the reader of the paper thought he had a sugar in which bacteria would not grow he was doomed to disappointment; the only fortunate thing was they would not produce a great deal of toxin under those conditions. It was not wise to attempt to prove too much, for such efforts only served to hinder the introduction of a product to the profession; and thus prevented the use of a food or drug which had certain valuable properties for the treatment of the sick.

Dr. CHARLES HENDEE SMITH said he thought the patient who tolerated 10 ounces of glucose showed a very high tolerance. He understood that 150 to 200 grams of glucose was a very fair measure of a child's tolerance, and a patient who could take 250 grams had an increased sugar tolerance. This might be due to hypopituitarism. It had been found that pituitary cases could take as high as 300 grams of glucose.

Dr. PORTER, in closing the discussion, said he did not wish to convey the idea that this particular glucose was a panacea for all kinds of disease. The facts he had tried to establish were whether one could use large amounts of glucose and not have it lost in the feces and how much glucose the individual could tolerate without producing glucosuria. During the last four months he had given over four hundred pounds, and some of the patients to whom this sugar was given were in desperate condition with cardiovascular disease and albumin in the urine. One patient whom he thought would not live two weeks had dropsy extending up to the shoulder blades, dyspnea, and severe pain over the heart. After taking the glucose, without any other change in medication and diet the patient showed decided improvement. In three or four weeks the dropsy disappeared and she was able to go away to the country. The albumin had dropped 75 per cent. At one time during the treatment the glucose failed for three or four days (this was early in these investigations when the supply of the preparation was limited) and the albumin immediately increased. As soon as some more glucose was obtained and taken again the albumin at once decreased, dropping again 75 per cent. He had seen that happen in a large number of cases. The point he wished to bring out was that glucose in the absolutely pure state could be given in large doses without producing loss of sugar in the feces or producing glucosuria and without exceeding the blood tolerance. Glucose was not a panacea, but it would slip directly into the blood and produce the same effect that all glucose did, increase heat production, and one could obtain heat and dynamic energy from it easily and more quickly than from anything else except alcohol. In relation to bacteria, Dr. Gies remarked that housewives in general knew that sugar had a preservative action and that this was due to its special action in connection with bacteria. When one approached a saturated solution of glucose the bacteria did not like it and stopped acting or disappeared; whereas it was a well known fact that weak glucose solution enhanced the activity of certain kinds of microbe life.

Moving Pictures Illustrating the Process of Drying Milk.—Mr. ATERBACKER made this contribution to the program. The films demonstrated the process by which

the dried milk was manufactured and emphasized the fact that dried milk acted like mother's milk in the infant's stomach. Dried milk was free from bacteria, rich in vitamins, and provided a biological substitute for mother's milk.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held October 27, 1920.

THE PRESIDENT, DR. HERMAN B. ALLYN IN THE CHAIR.

Symposium on National Health Insurance.

The Medical Aspects of National Health Insurance.—Dr. FREDERICK L. HOFFMAN, Prudential Insurance Co. of Newark, N. J., delivered this address in which he stated that there were at least two sides to this question and he was afraid that the conflict of views did not permit of a reconciliation. As the result of Health Insurance Legislation in England the new viewpoint was strongly in favor of the reorganization of the British medical profession on the basic principles of a trades union and the adoption of a fighting platform including the threat of a strike. The negotiations in behalf of better terms, of a modification of the regulations, and of other matters, were practically as endless as they were seemingly helplessly confused. Letters contributed within the last few days to current medical literature would suffice for the time being to answer the preposterous assertions that panel practitioners throughout England were satisfied with the workings of the National Insurance Act. He was as familiar as anyone with the fact that a large proportion of panel doctors had derived a material share of pecuniary benefit from National Health Insurance. The doctor who practiced among the poor with a bottle of medicine and gave, broadly speaking, largely worthless treatment no doubt had a hard time of it in collecting his bills. He now had an assured income and did not need to worry about competition or the stress and strain of professional skill, for in place of the old time discredited doctor had come the panel doctor who, with the sanction of the State, was engaged in lowering the dignity of the medical profession to the status of a trade bearing the obvious stain of cheapness. Standardizing medical practice was a perilous procedure. The panel patient was the slave of the panel doctor and the panel doctor was the slave of the panel patient and both were in absolute bondage to the countless rules and regulations of the Ministry of Health. No one who valued the high status of the medical profession in America and was determined to maintain it could contemplate without serious concern the remote possibilities of a similar state of affairs in this country. No conclusive evidence had been forthcoming from any responsible source that public or personal health in England had been improved in consequence of National Health Insurance Legislation. Although the Act in its preamble emphasized the viewpoint that the objective was the prevention of diseases, nowhere in the Act was provision made for methods or means whereby disease as such could be prevented. The outlook in England was discouraging and not far from desperate. Unemployment was increasing at a prodigious rate while Poor Law expenditures were mounting to prohibitive proportions. Just as on the one hand there had not been the anticipated improvement in public health, so on the other there had not been the expected diminution in Poor Relief. A large and increasing proportion of paupers among insured persons were cared for in Poor Law institutions. The writer said he had gone from bedside to bedside of panel patients. He had interviewed scores of panel doctors. He had examined hundreds of reports of sickness visits, and in his judgment the system was not only a grotesque failure, but a frightful imposition upon British wage earners entitled of right to conditions more effective in promoting health and longevity.

Economic Consequence of Illness.—WILLIAM DRAPER LEWIS, Esq. of Philadelphia, delivered this address in which he said that poverty had a great many causes and we had to deal with it, so it seemed to him at least, as doctors dealt with sickness, not by one panacea for all human bodily ills, but by analyzing the

causes of poverty and eliminating one at a time. When he started to study this subject he knew that sickness was the cause of poverty just as poverty was the cause of sickness. He had had that idea and also had known that in Germany, in England, and in other countries they had had something they called Health Insurance, sometimes voluntary, sometimes compulsory. It had therefore seemed to him worth while and interesting to go one step further and even to do something about these matters and, therefore, he had been influential in the appointment of a Health Insurance Commission which had been appointed under the Act of July 25, 1917, by the predecessor of the present Governor. In the first place the Commission had gotten the Pennsylvania School for Social Service in Philadelphia to make a sickness survey of a district in Kensington. That took the entire time of some 50 persons who visited between 700 and 800 families and got their sickness history for the year. They found that the average person had lost from sickness an average of 38 days. Now a sickness of 2 or 3 days was not serious but a sickness of 38 days to a working man with a family was a very serious thing. What really happened was that the wage earner thought that he could not afford to be ill, and that, therefore, the man stayed at work when he ought not to have been at work, and, as a result, when he got sick, his sickness was longer and therefore reached an average of 38 days in this Survey. They found that the employee who became ill obtained very little help from his employer. It was also found that the fraternal insurance societies and the labor unions had been of very little financial benefit to those of their members who had suffered illness.

National Health Insurance from the Physician's Viewpoint.—Dr. J. E. SWEET of Philadelphia read this paper in which he stated that his remarks were based on a study of the bill drafted for the State of New York and sponsored by Senator Davenport, and therefore known as the Davenport Bill. One reason why he felt that he should confine his remarks to that particular bill was that he could see no way in which it could be improved upon except by hitting it hard upon the head. He meant that it was a carefully worked out plan and apparently all the objections to such a scheme, such as were manifestly inherent in the competitive bidding schemes of the Continent, had been carefully considered and avoided. He would make the assertion that such a scheme could not work because it was unjust to the insured and because it was in conflict with the fundamental principles of medical practice. In addition to the financial duties of the Board which it was proposed to establish it was designed that it should employ one or more medical officers, who should be legally qualified physicians, and who should possess such other qualifications as the Board with the approval of the Commission might prescribe. It was further proposed that no medical officer should practise medicine in any capacity. These medical officers were personally to examine patients, obtain statements from the attending physician, and then issue certificates of disability; the physician in charge did not issue these certificates. One could see here a beginning of trouble for the general practitioner, such as disagreement as to the degree of disability, etc. The writer stated that such a plan was unjust to the insured. He arrived at such a conclusion from a consideration of the facts of disease. He called attention to the fact that the person who was careful of his health would be compelled to pay for the sickness of those who got sick because of lack of care. He stated that this proposed act was in conflict with the fundamental principles of the practice of medicine. The act provided that all employees under the meaning of the act should be insured without medical examination. This meant that the malingerers and the chronic invalids would be the first patients of a physician who undertook to work for the Fund. Now a practitioner of medicine or surgery succeeded in proportion to his success and his success was measured by the cases he could cure. No man could afford to undertake to treat a clientèle composed of malingerers and the hopelessly ill. Even the success of the best of physicians might be placed in jeopardy by a small series of fatal cases. In addition to this con-

flict with the principles of practice another serious one arose under the provisions of the act, namely, the necessity of practising under the supervision of a medical officer. No self-respecting physician would treat a patient and then have some third person step in to control and pass upon his work; not because the physician feared to have his work passed upon, but because he knew that the relation between doctor and patient was a personal relation and was so recognized in law. The entry of a third person destroyed this acknowledged relationship. The insured would not only be unjustly forced to pay for the cost of his neighbor's carelessness, but he would be forced by the natural workings of such a measure into the hands of the very young in the profession; or into the hands of the older incompetents; instead of obtaining better service he would inevitably obtain worse service than he did today. The trend of modern medical teaching was toward a method of practice such as we had seen in the army; but if you wished to apply your army methods to your private practice you would last as a practitioner of medicine just about 15 minutes. One of his objections to such schemes as National Health Insurance was that they unavoidably tended to create conditions of practice approaching the army conditions. To correct existing defect we must go farther away from such conditions, not try to approach them.

Mr. ORDWAY TEAD of New York City said that certainly the conclusions Dr. Hoffman had reached about the duty of the medical profession of England towards the operation of the British Act were not in accordance with the attitude of the British profession. He said that Mayor Ramsay of Chester, Pa., Chairman of the Health Insurance Commission of Pennsylvania, and himself had spent a month in England for the purpose of investigating this subject. It was found that a negligible number of individual people had any strong, reasoned opposition to the British Health Insurance Act. They had found no organized group opposed to it. One might say that among certain groups, for instance employers, there was a degree of difference. The Trade Unions, with a membership of 17,000,000 in all, were very enthusiastic for the extension of the benefits which the act offered. Dr. Alfred Cox, Secretary of the British Medical Association, said that one could not drive the British doctors away from the British Insurance Act with a crowbar. Out of the 25,000 doctors in Great Britain 14,000 were on the so-called Panels practising on full or part time. There were doctors for the medical work for school children, for tuberculosis, for venereal diseases, for maternity and prenatal care, provided for by joint contribution of the National Government and the local authorities. Recently an appointment of 30 doctors was to be made. There was sharp competition and no less than 1,300 physicians applied for these 30 places. The doctors of Great Britain were not opposed to Health Insurance so far as Mayor Ramsay and he could find out, although they had been opposed to it 10 years ago.

Dr. HENRY D. JUMP of Philadelphia said that except for a moderate comparison the condition of affairs in England did not concern us here, for, if the Davenport bill as offered in the New York Legislature was the last word which had been given in regard to this matter, we must judge of its effects upon us by the Davenport bill and not by the working of the Act in England. There were one or two points made in the last speaker's address which ought to be answered. Dr. Cox might be the mouthpiece of the medical profession of Great Britain, but he imagined that Dr. Cox was no more the mouthpiece of the physicians of Great Britain than Alexander R. Craig, in Chicago, was voicing the opinions of the physicians in this country. Dr. Craig had his own opinion and we had ours, but he was not telling the profession what they thought, and the speaker imagined the analogy was almost perfect. He believed it was true that many of the British physicians were satisfied because there was more or less of an established income and one had simply to look to the physician's income in our mining towns to see the same sort of attitude. It was not, however, conducive to good medical practice to work under such conditions and the County Medical Society was standing for good practice rather than

increase of income or assurance of income. As Dr. Lewis had pointed out, there were two particular points on which he based his advocacy of such legislation: (1) that sickness was the cause of dependency in a greater percentage than any other single cause. Let it be granted that this might be so, but was the remedy that which had been offered? Was it not rather more adequate returns for service rendered; that is, better wages, rather than more charity? (2) That the workman could not afford to be ill. He could if he was being paid. And would he be better cared for or could he afford to be cared for by the sort of physicians he got under the English Panel system? If we approved of insurance for sickness, why ought we not provide against sickness by establishing an insurance fund for coal, because, if the individual was not properly warmed, he might become sick; and, by the same token, let us provide this poor devil of a working man with clothing. He needs an overcoat and he ought to be fed; let us provide him with meat and potatoes, and, carrying the thing to the ultimate conclusion, let the beneficent State paternally decide what shall be done with the various proportions of the weekly wages which he receives.

WILLIAM DRAPER LEWIS, Esq., said that they as a Commission had not at the present time, so far as he knew, any definite remedy, but that they did see the evil and wanted enlightenment from the workmen, from the manufacturers, and from the doctors. They wanted help; they invited the doctors to try to help them. That was the attitude which he thought every Commission of the kind should take in every part of the State. If the doctors did not come in and help and give testimony such as they had given tonight, they would have only themselves to blame if in the end some legislation was put through in ignorance of the fundamental principles of the healing art.

Dr. J. E. SWEET of Philadelphia, said that he would like to express his admiration for any man, or any group of men, who could in one month's time find out what a real Englishman thought about anything. He said that he had just recently come back from 22 months service behind the British Front with the British Medical Corps. He did not recall that he had found among the medical officers of Great Britain any who were in favor of the English Panel system and he did not think any of the medical officers were panel doctors. He supposed the panel doctors were very busy, at any rate they were not at the Front.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

THE ANATOMY OF THE HUMAN SKELETON. By J. ERNEST FRAZER, M.D. 284 pages with 219 illustrations. Published by P. Blakiston's Son & Co., Philadelphia.

CLINICAL OPHTHALMOLOGY FOR THE GENERAL PRACTITIONER. By A. MATTIAND RAMSAY, M.D. 500 pages with illustrations. Published by Henry Frowde and Hodder & Stoughton, London.

A TEXT-BOOK OF PHARMACOLOGY AND MEDICAL TREATMENT FOR NURSES. By J. M. PORTESCUE-BRICKDALE, M.D. 392 pages with illustrations. Published by Henry Frowde and Hodder & Stoughton, London.

COMMON INFECTIONS OF THE KIDNEYS. By FRANK KIDD, M.D. 331 pages with illustrations. Published by Henry Frowde and Hodder & Stoughton, London.

TROPICAL OPHTHALMOLOGY. By ROBERT HENRY ELLIOT, M.D. 525 pages with 117 illustrations. Published by Henry Frowde and Hodder & Stoughton, London.

CLINICAL LECTURES ON ENLARGEMENT OF THE PROSTATE. By Sir PETER J. FREYER, M.D. 174 pages with illustrations. Published by William Wood & Company, New York.

AN INTRODUCTION TO THE STUDY OF HYPNOTISM. By H. E. WINGFIELD, M.D. 195 pages. Published by William Wood & Company, New York.

Miscellaneous

The Physician in the Year 1300.—Zimmerlin relates in the *Schweizerische medizinische Wochenschrift* for October 21, 1920, i, 43, that a work in Latin by De Thessolis, a preaching friar, composed about 1290, was subsequently translated into German by another cleric named Von Ammingen, who, by adding matter of his own, gave it the status of a new book. The subject of the book was the game of chess which had recently been introduced into Europe and was attracting great attention. The manuscript volume, all in Von Ammingen's handwriting, number 264 pages, and the chessmen were used to illustrate moral subjects. The editor or author relates the interesting fact that he went to Montpellier to consult the famous Bernard Gordon about his health. Incidentally are found many details of the culture of the period, including the practice of medicine. We find the essentials which a medical man of the time must possess. The physician was expected to be versed in the following subjects: Grammar, logic, rhetoric, geometry, arithmetic, physics, astronomy and theology—the equivalent of the M. A. degree of the present time. Reasons are given why each of these branches is necessary. If he does not know arithmetic the physician will be unable to count the pulse beat. Astronomy teaches him the optimum time to give a drug. Theology is necessary because some men are ill by reason of their sins, while belief in Christ will often heal disease. The physician, contrary to what we are often told, should carry a surgeon's outfit and be able to treat wounds. A proverb of the day was to the effect that there are more bungling workmen among physicians than in any other class of handworkers. In other words, at that period there was no apparent demarcation between medicine and surgery. Every man wanted to practise medicine.

The medical man must be industrious and see his patients often, must know the signs of both sickness and health, must know the occupation and habits of the patients and must urge the latter to make a clean breast and keep nothing back. He must be versed in the works of the masters and follow their precepts. He should know thoroughly a number of books—a sort of "five-foot shelf," by no means all technical. Several well known works by theologians are mentioned. Rules for bedside conduct abound, all more or less trite. There were erroneous viewpoints among the craft such as attributing greater virtues to exotic drugs. Sharp practice was seen at times, as when a physician promised to cure a woman of an ocular disorder in return for a contingent fee. As the patient was apparently unable to see, the doctor slyly took with him at each visit a souvenir, possibly hedging against failure of the adventure. The woman recovered, but refused to settle, whereupon he brought suit to recover. She testified that he had purloined articles of beaten silver, saucers, etc., and the judge ordered him to return them on penalty of death for non-compliance. She also testified that he had promised to restore her vision to its original normal state and had not done this; nevertheless on returning the goods he was paid his fee.

Dr. Aragon Y. Muñoz, who died last August in Havana, was a member of a family distinguished

in science and literature. He was born in Cuba in 1868 and took his bachelor's and medical degrees in the University of Havana as well as a degree in pharmacy. In New York he was a student in the Lying-In Hospital and began practice in Jacksonville in 1898. After the close of the Spanish war he removed to Havana and began the practice of surgery and obstetrics. In 1902 he was made chief sanitary inspector and was in charge of several obstetrical services. He entered into medical journalism, collaborating with the late Dr. Enrico Nuñez and was active to the time of his death in practising and teaching obstetrics, in sanitation, medical journalism, medical society work, and other public activities. Two sons are well-known Havana physicians.—*Cronica Medico-Quirurgica de la Habana*.

Androgynes and Gynanders.—Professor Laiguel-Lavastine lectured on this subject last spring from the viewpoint of a psychiatrist, his lecture having appeared in *Le Progrès Médical* for Sept. 11, 1920, xlviii., 37. The occasion was a case of Apert's hirsutism—a so-called bearded woman, with further examples of atypical sex ensemble. The frame was masculine, the clitoris hypertrophic, and there was amenorrhea. The age was 21, mentality imbecile; there was inability to learn in school or to work for a livelihood. Another patient studied for comparison was a male, aged 19, weak physically and psychically, choleric and a deaf mute. The woman wore a beard and moustache, while the man had a smooth face. He presented cryptorchidism and a very small penis. The woman showed a masculine disposition and small breasts, narrow hips, male type of pubic hair. The clitoris was phallic in appearance while the labia resembled a scrotum when approximated. However the scalp hair was feminine. The male or androgyne on the other hand had buttocks and thighs which resembled the female type and the female distribution of pubic hair. There was a slight suggestion of hypospadias seen in incomplete coalescence at the middle line of the scrotum. The female or gynander presented redundancies and the androgyne presented defects. The gynander in this case resembles considerably the acquired condition known as supraprenal virilism. Androgynes are much more often seen than gynanders. The former may exhibit great extremes. For instance, an apparently typical woman may have one testicle or both. There are three types of pseudohermaphrodites from the viewpoint of sexual attraction. In one the subjects are almost or quite sexless. There is a testicle but its development may be very slight. In the second or orthosexual type the disposition agrees with the kind of gonad. As this is most commonly male many of the androgynes, although they may resemble girls, are attracted by women. In the third type we have homosexual or inverted pseudohermaphrodites, in which, despite the presence of a testicle, attraction is toward the female. Thus a gynander without any evidence of male gonad may be attracted to women and may even marry. The clitoris may be large enough for relations with women but the marriage will of course be sterile. The author does not mention the kind of gonad called the ovotestis which is found among these subjects and adds to the confusion.

A CASE OF MULTIPLE MYELOMA WITH UNUSUAL FEATURES.

By VERNON C. BRANHAM, M.D.,

NEW YORK.

PHYSICIAN TO THE PSYCHIATRIC INSTITUTE;

AND

NOLAN D. C. LEWIS, M.D.,

WASHINGTON, D. C.

PATHOLOGIST TO ST. ELIZABETH'S HOSPITAL.

MULTIPLE myelomata, because of their diffuse extension and bone cortex erosion in various parts of the skeleton, necessarily give rise to many peculiar features. Among the post-mortem examinations made at St. Elizabeth's Hospital during the past year one such case attracted the attention of the writers—a case simulating brain tumor with pronounced unilateral exophthalmos. The true nature of the case, unfortunately, remained unrecognized until brought to autopsy. A résumé of the clinical history follows:

P. C., age 26 years at time of admission to St. Elizabeth's Hospital July 9, 1882, suffering from auditory hallucinations, periods of intense psychomotor activity, and a general dementia of moderate grade. His excited periods occurred about every three weeks and would last some four or five days, during which he would become belligerent and destructive to an extreme degree. The interim was, relatively speaking, an emotional calm characterized by talkativeness, laughing to self, typical precox reactions, and some retardation. He was able to perform many of the routine duties in the ward. This condition obtained over a period of many years, the stages of unrest becoming less frequent and less stormy and the apathetic stretches more in evidence. Irritability superseded excitement as the dementia progressed beyond the stage of active hallucinosis. His physical condition remained excellent throughout. On February 14, 1906, the patient jumped over the stair banister on the way to meals and sustained a severe contusion of the right ankle and hip. This responded well to treatment and apparently no complications developed. At this time, on the mental side, he was completely disoriented in all fields, showed marked impairment of memory, and reacted to both visual and auditory hallucinations. Dental trouble first developed in July, 1908, at which time two teeth were extracted, and frequent trips to the dentist became necessary thereafter. The mental situation took on an added interest during this period through the appearance of delusions of grandeur and poorly organized ideas of persecution. For the first time the patient became untidy and would spend hours lying idly on the floor. On March 30, 1913, he had an illness of three days' duration, characterized by headache, chilliness, general malaise, and a moderate elevation in temperature. He was still being treated for pyorrhea, and in January, 1916, two more teeth were extracted. At this point the physical machine began to run down very rapidly. On May 2, 1916, the patient had a swollen face, some elevation in temperature, and headache. The condition was provisionally diagnosed as dental caries

and a tooth was extracted. On July 21, 1916, a more severe attack confined him to bed, his face being swollen to the extent that the right eye was completely closed. This attack lasted six days. On February 12, 1917, a third attack of two weeks' duration occurred, in which the entire face and neck were involved. A maximum temperature of 103 degrees was attained. The condition was diagnosed as erysipelas. A similar attack took place on November 17, 1917, if anything more severe than its predecessors. His mental status had remarkably altered during this period of two years. The patient became quiet, orderly, very agreeable, and willing to work in the dining room. Much of his indifference to environment disappeared, although he remained seclusive and inaccessible. His hallucinatory experiences receded into the background and seemed to be replaced by a general feeling of contentment and well-being. On July 15, 1919, he became a permanent bed patient because of enfeeblement and untidiness. September 29, 1919, for the first time the patient complained of his right leg hurting him. Examination showed enlargement of the right hip with no evidence of a tumor growth. A moderate degree of tenderness was present. Three weeks later exophthalmos of the left eyeball was noticed; although there were no signs of general intracranial pressure, a brain tumor was suspected. Impairment of vision was early noted. A well defined immovable tumor the size of a hen's egg over the region of the right trochanter was present by this time. After a more or less prolonged period of asthenia the patient died on December 22, 1919. Laboratory examinations showed a doubtful Wassermann (blood) in June, 1915, a few granular casts and a trace of albumin in the urine, and an absence of parasites in the feces. It is much to be regretted that the urine was not repeatedly examined for Bence-Jones protein, and that the mental condition of the patient made physical examinations very difficult.

Discussion of the Case.—From a clinical point of view this case presents several questions of interest, among which may be discussed: 1. What factors in the patient's history might have a bearing on the etiology of the tumor growth? 2. Is there any relationship existing between the physical and mental sides of the case? 3. Are there any remedial measures which might have availed?

Of interest to those who hold to the theory of the traumatic origin of tumors is the history of an injury in February, 1906. On that date the patient jumped over a banister and sustained a severe contusion of the right ankle and hip. A fracture was not present, and apparently no untoward results occurred, as the patient recovered full use of his leg after two weeks' rest in bed. It is noteworthy that a period of thirteen years intervened between the injury and the first appearance of tumor symptoms at the site of injury. Such a quiescent interval is unusual although not impossible. Unfortunately it permits many other factors to creep in which may cast doubts upon the injury being the true etiologic factor.

Adherents of the irritation theory of the origin of malignant growths may modify this view to the

extent that the injury lowered the vitality of the tissue cells, more especially those of the lymphoid elements in the bone marrow or at least established their metabolic equilibria on a different level, that these altered cells remained below par and continued

FIG. 1.—Showing matting together of the median lumbar lymph glands about the lower portion of the aorta.

to produce cellular tissue below par until such a time as a constant source of irritation in the form of toxemia from repeated attacks of erysipelas came into effect; that this constant source of irritation stimulated the defective cells to overgrowth with the ultimate result of malignant changes.

If we may carry this investigation a step further a rather significant chain of events presents itself to followers of focal infection ideas. This may be tabulated in the following sequence:

Dental Trouble

1. July, 1908—two teeth extracted.
2. 1908-1912—frequent trips to dentist for treatment of pyorrhea and caries.
3. March 30, 1913—cellulitis of jaw, moderate elevation of temperature. Some doubt as to nature of attack. Possibly abscessed tooth. One tooth extracted.
4. January, 1916—two teeth extracted.
5. May 2, 1916—one tooth extracted.
6. February 7, 1917—treated for pyorrhea.

Attacks of Erysipelas.

May 2, 1916—moderately severe attack of erysipelas, patient in bed one week.

February 12, 1917—severe attack, patient in bed for two weeks.

November 17, 1917—entire head and neck involved—maximum temperature 103°.

Of some significance is the attack of March 30, 1913, which seemed to occupy an intermediate position between the symptoms of an abscessed tooth

and a mild form of erysipelas. Some connection between the two conditions appears to be probable. The line of march, then, would be a history of definite trauma to hip and general lowering of cellular resistance and pyorrhea and dental caries extending over a period of five years, which ushered in four sharp and well defined attacks of erysipelas. Two years later malignant involvement of the right femur took place.

The more or less causal relation existing between sarcomata and erysipelas may be recalled at this point. Coley's experiments with injections of erysipelas sera into malignant masses are familiar, however obscure may be their meaning or however futile their therapeutic value. In consideration of the close association of sarcomata and myelomata, it is not wholly an effort of the imagination to conceive of some such relation as we have just mentioned, existing between erysipelas and myelomata or other bone marrow tumors. That on occasion erysipelas should have a salutary effect upon this type of connective tissue tumor, and in other instances that it should be the exciting cause, is somewhat paradoxical. This whimsical twist in the affairs of tumors is commonly observed, however, and Coley himself met with many surprising reversals in this respect.

Perhaps a word here should be said concerning myelomata and the leukemias. Among the pathological conditions affecting the lymphatic tissue the so-called blood diseases known as the leukemias stand at one extreme, while the pseudo-leukemias and myelomata stand at the other. The one ex-

FIG. 2.—View of base of skull with tumor in left anterior fossa.

hibits a maximum change in the blood picture and a minimum hyperplastic formation. The other presents the opposite condition. The transitional stage between these two groups is met with in forms such as the leucosarcomata and chloromyelo-

sarcomata in which blood changes and hyperplasia reach a more even balance. It is this relationship which has led many investigators to classify boldly the leukemias among the tumor growths—a malignant hyperplasia of the lymphatic tissues, fluid or

FIG. 3.—Tumor mass growing in orbit pushing the eye from its socket.

otherwise. This particular case, with its lack of metastasis, occupies the border line between the myelomata and the above-mentioned transitional group. The distinction, however, is too fine to be worthy of further comment. If myelomata, as the above discussion would seem to indicate, may be considered as one of the end results of aberrant changes in the lymphatic portion of the circulatory system, Ribbert's hypothesis of the disturbance of equilibrium of tissue may have a bearing on the etiology of this special tumor. Briefly stated, the injury to the hip probably produced a relaxation and an alteration in the density of the local structures which freely allowed subsequent erosion. Such infiltration threw an undue stress upon the lymphogenic elements in that locality, which response ended in overstimulation, overproduction, and finally malignancy.

Our second point of discussion concerns itself with the correlation between the physical and mental sides of the case. During the years 1916 and 1917, at the time when his acute illnesses were in greatest evidence, we are confronted with a remarkable change in the mental status of the patient. From an irritable being, highly excitable, quarrelsome, unwilling to work and most actively hallucinated to an orderly patient, efficient in ward work, agreeable and showing but a slight hallucinosis, was a matter of days—days measured in terms of erysipelas and extracted teeth. Cases similar to this can be adduced by everyone dealing with mental diseases. The writer has in mind a case confined in one of the disturbed wards for several months. Rather suddenly he developed a suppurative condition of his left submaxillary glands. Extensive dissection under a general anesthetic along the cervical fascial planes was necessary to give adequate drainage. Following this episode (during which a relatively high grade of toxemia was attained) the psychomotor unrest which was such a prominent and persistent feature

previously, showed marked amelioration, and for several weeks thereafter he was able to maintain himself at the level of paroled patients. The patient later regressed but not to his former status. A second instance is that of a catatonic dementia precox for several months on the detached service of St. Elizabeth's Hospital—a severe infection of one of his fingers required several incisions. This treatment brought him out of his retarded condition and in two weeks no active psychotic symptoms were apparent. In such cases whether the toxemia produces a stimulating effect upon the central nervous system or, as in the precox case, whether the pain attendant upon the injury was sufficient to focus attention upon reality for a time long enough to bring the patient out of his psychosis is a matter of some comment.

As this disease is of general distribution through the bone marrow and often spreads through the viscera, the usually advised therapeutic measures, such as amputations, excision of local growths, x-ray treatments, etc., are of course valueless.

General Postmortem Findings with Description of Histopathological Features.—The appearance of the body was that of an aged male of medium size bearing a skin covered with discrete purpuric spots and numerous brownish pigmentations of general distribution and of the type indicating adrenal disturbance. The left eye was hard, bulging, under tension, and the pupil was pin-point in type. The right eye presented the usual slightly dilated pupil, and was otherwise not remarkable. The right hip was dislocated, the leg rotating outward and the knee was swollen and presented a

FIG. 4.—Nodular tumor developing about the upper one-third of the femur.

"floating" patella. A large, firm, irregular growth was palpated on the upper third of the femur.

Heart.—The left ventricle wall was slightly hypertrophied, containing a moderate amount of interstitial replacement. The mitral valve showed some stenosis with marginal thickenings of the cusps, and the aortic

areas presented a few elevated yellowish plaques of small size. The arch and descending aorta exhibited a diffuse red lining, the continuity of which was broken by small, rather deep ulcers. The lower six inches of the aorta, immediately above the iliac bifurcation, was moderately contracted, as were also the iliaes, the left

FIG. 5.—Showing arrangement of cell groups and the distribution of the reticulum in the tumor on the neck of the femur.

being distorted and deviated from its course by massive swelling and infiltration of the surrounding median lumbar glands, which contained and were nearly replaced by firm grayish hemorrhagic tumor metastasis. (See Figure 1.) Microscopically the heart sections exhibited a large amount of intermuscular fibrous replacement with a moderate compensatory hypertrophy on the part of the muscle cells, which were swollen, containing large nuclei, and were irregular in contour. There was a moderate amount of segmentation.

Respiratory System.—The lungs were swollen and presented prominent lobulation, the anterior surfaces being mottled by large patches of dark red hemorrhagic spots. Gross sections showed a very marked edema, with much oozing of free fluid and an intense congestion in all portions; early elevated gray granular patches were seen in the bases. All bronchi, with the trachea, bore a congested mucosa, and a dark brown exudate was present in the branches. Microscopical sections of the lung showed diffuse congestion throughout and in many places collections of air sacs were filled with red blood cells and polymorphonuclear leucocytes. In other portions of tissue the patches contained chiefly pus cells, and the alveolar walls showed acute congestion. Some portions of the lung were emphysematous. The bronchioli were closely packed with pus cells and their walls were infiltrated with the same. Near one of the peribronchial cartilaginous plaques were seen two localized accumulations of cells, myelogenic in type and resembling very closely the type of cell described under the tumor sections. These cells were arranged loosely without stroma and were perhaps localized metastases from the bone marrow.

Liver.—Presented a normal capsule through which the lobulation of the organ was easily visible. Sections of the liver substance showed bile staining about the portal canals, and an easily visible diffuse fatty change with an interstitial tissue increase. The gall bladder was small and contained two large-size dark, irregular stones, surrounded by thick orange colored bile. Microscopically the organ showed patches of extreme degeneration in which the liver cells were entirely destroyed and the tissues appeared extremely areolar in structure. This fatty change was particularly evident about the portal canals. There was some general shrinkage of cells throughout the organ and fine, diffuse fatty changes in nearly all hepatic cells. No tumor metastases were present.

Spleen.—Was small-sized and swollen, the capsule was gray and studded with small elevated cartilaginous bodies and the substance was homogeneous, dark red, and was much softened through the central portions. Microscopically there was a moderate diffuse

deposit of blood pigment and all of the sinuses and vessels were choked with blood.

Pancreas.—Large, soft, pale, presenting a substance streaked with prominent capillaries. There was an encapsulated white fatty concretion near the pylorus of the organ, about the size of a hazelnut. Central portions of this body contained calcareous masses surrounded by fatty substance. Microscopically the general appearance of the organ was not remarkable.

Stomach and Intestines.—Were not remarkable and the mesenteric lymph glands were all normal with the exception of those described below under the tumor formation. Mesenteries contained much fat and all organs were embedded in a large amount of this tissue.

Kidneys.—Both kidneys were enlarged, dark red and swollen, with the capsule moderately adherent. Many cortical cysts of various sizes, some containing clear fluid and others dark brown cloudy substance, were present over the surface of the organs. The cortex was granular and fatty in appearance and all vessels were large and sclerotic. Microscopically the kidney exhibited a capsule which was at least four times the usual width, and contained a few hyaline vessels. Extending from the surface to the upper layers of the cortex were seen patches of fibrous tissue which enclosed and partially destroyed groups of tubules and glomeruli. This tissue showed great congestion of the recently formed capillaries and there was fibrohyaline degeneration of many of the enclosed elements. A few large cysts filled with hyaline material were seen deeper in the substance and many glomeruli had undergone hyaline degeneration. Vessels were everywhere sclerotic and hyaline in type and also engorged with red blood elements. Tubules were flattened and many were lined by an extremely flattened type of cells bearing linear curved nuclei.

Bladder and Prostate.—Appear normal.

Adrenal Glands.—Were greatly enlarged and very

FIG. 6.—Section from vertebrae (low power) showing masses of soft fatty cells extending through the substance.

dark brown in color, with a thin cloudy cortex which was softened and edematous. The medullary portions were notably diminished, light in color, and partially liquefied. Microscopically the cortical zones were much widened and throughout the entire gland there was diffuse cloudy swelling of all cells. There

was an occasional lymphoid infiltration, with also many fatty changes in the middle zone cells. The medullary portion was much reduced in amount and contained many fibrous replacements and small patches of lymphocyte accumulations.

Thyroid Gland.—Normal in size and appearance. Microscopically the relations of the colloid and interstitial tissues were fairly well preserved but the colloid was distributed in smaller follicles than usual and there was some proliferation of chief cells and a diffuse congestion of the capillaries of the gland.

Pituitary.—Presented nothing remarkable.

Head.—Removal of the calvarium disclosed a flat new growth infiltrating the left parietal zone. This tumor was reddish in color and specked with white, containing many bone spicules, which were visible only at the inner surface. The outer table of the bone showed only a localized discoloration. The size of this growth was 4 x 6 cm. and it was quite irregular in contour. It had apparently produced very little pressure on the brain which was not remarkable except for the presence of general edema with cloudy swelling of the cortex. The brain, however, was slightly adherent to the base of the left frontal fossa where a large mass of tumor growth protruded from the surface of the inner table. This mass was flat but extended over the entire fossa and back over the wings of the sphenoid. (See Fig. 2.) The section showed this tumor to have eroded the left sphenoid wings, nearly destroying all the bones of the orbit and has passed through to the exterior, going behind the zygomatic process, and pushed its way into the orbital cavity where it was closely adherent to the posterior aspect of the eye globe (Fig. 3), pushing it forward and destroying both the bony and soft tissues. The eye was surrounded with large fatty accumulations and much connective tissue overgrowth, the sclera, iris, and a portion of the cornea being replaced by these structures. The ethmoid and sphenoid sinuses were infiltrated by this neoplastic tissue, the nature of which was evidently of bone marrow origin.

Tumor of the Femur.—The neck and the upper third of the right femur were surrounded by a large overgrowth of bony, fibrous structure, firmly adherent to the adjacent tissues. This tumor was very firm, nodular, grayish red in color and completely surrounded the shaft (Fig. 4), the mass measuring 8 cm. in longitudinal diameter.

Longitudinal section disclosed the picture of extensive local erosion and destruction of the cortex of the bone, remnants of which were still present as spicules. The marrow, both downward through the shaft of the bone, and upward through the head, was largely replaced by soft, hemorrhagic new growth containing many spicules of bone. The growth was seen extending through the ovoid depression for the ligamentum teres, the margins of which were softened and eroded, and the acetabulum was filled with the growth which extended through the marrow of the ischium and ilium, finally breaking through the ilium into the abdominal cavity where it had limited its gross metastasis to the median lumbar lymph chains. The cortices of the above mentioned bones, as well as those of all the vertebrae were thinned out, fragile, and cut very easily. The central portions of the vertebrae were very soft, hemorrhagic, and oozed much fluid. Apparently the extension of the process through the bone marrow in all directions was not limited.

Microscopical Examination of Tumor Growths: Lumbar Lymph Glands.—The capsule of the gland was deeply infiltrated by streaks of medium sized irregularly spherical cells, having a relatively large amount of pink stained protoplasm and an oval, usually eccentric nucleus which was sometimes deeply stained, showing no architecture, and in other portions presenting coarse chromatin granules. In general the cells were arranged in large groups surrounded by thick bands of interstitial tissue, but in some places the cells were separated by a finely dividing stroma into groups of three or four cells each, producing a suggestion of an adenomatous appearance of the structures. In areas there was a large amount of hemorrhage and orange colored pigment deposit among the cell groups. The entire gland which showed throughout an increase in supporting tissues, and an irregular endarteritis proliferans of its arteries was nearly replaced by two meta-

static growths, there remaining only an occasional remnant of the former lymphoid follicular structures.

Microscopical examination of the thoracic and mesenteric lymph glands showed no gross infiltration of tumor cells, but myelocytes and endothelial leucocytes were quite abundant. The general architecture of these glands remained normal, with perhaps a rather diffuse distribution of the lymphoid structures.

Frozen Section from Large Tumor on the Neck of the Femur.—The sections presented a solid mass of dense myelogenic cell accumulations with small strands of stroma extending between the groups of cells (Fig. 5). Small deposits of necrotic bone were occasionally encountered and in areas the tumor cells had massed and coalesced, and here produced an acidophilic staining reaction, but these places were relatively few in number.

Sections from Various Bone Marrow Sites.—They showed a general increase in myelogenic elements with enormous numbers of cells in stages of division. The marrow was diffusely infiltrated with free blood, and many groups of erythroblasts were seen distributed through the interlacings of the tissue. A great amount of pycnosis was noted about the nuclei of the lymphocytes and myeloblastic bone marrow cells. A few polymorphs were seen scattered through the field.

Section from Body of Vertebrae.—These sections presented a marked reduction in osteoid structure. In places with the exception of hemorrhage patches the bone marrow was normal in appearance. In other areas between the remnants of bone tissue was seen vast collections of myeloblasts, bearing a large amount of protoplasm, stringing together in a connected network, gyrating and dipping into the crevices of bone, portions of which were necrotic, unstained, and in a disintegrating state (Fig. 6). Occasionally large areas of bone marrow were entirely replaced by hemorrhage.

Conclusions.—1. As multiple myelomas are of particular interest from a chemical standpoint, because of the presence in the urine of Bence-Jones protein, it is to be regretted that this case was an accidental autopsy finding and no investigations in this field had been followed.

2. The case is of interest because of the unusual site of erosion in the bones of the orbit with the production of a pronounced unilateral exophthalmos which could have been easily mistaken for one of numerous other conditions.

3. It is also interesting that the only gross growth discovered outside of the bones was a dense infiltration of the medium lumbar lymph glands, probably a direct extension from the softened right ilium.

4. As is usual in these cases the actual origin of the cell is rather obscure, as is also the etiology of the disease. This type of tumor differs from the standard varieties of malignancy in that it seems to affect simultaneously the marrow of numerous bones diffusely and without usually producing a true metastasis.

In some instances there is a resemblance to the leukemias and pseudoleukemias and it is somewhat uncertain as to how the disease should be classified.

Vitamines and Inanition.—Lumière states that he has established the rôle of the vitamins in the body—or at least part of the rôle. This is the activation of the glands of external secretion. We know that withholding vitamins from the food results in gastroenteric disturbances severe enough to entail total inanition. At first sight this does not explain the polyneuritis and lesions of the cerebellum, but experiments have taught him that these accidents occur only on relatively sudden withdrawal of vitamins. He also fed animals insufficiently, but with abundance of vitamins, and obtained the same polyneuritic lesions, showing that these are really due to inanition and not to mere absence of vitamins.—*La Presse Médicale.*

WILLIAM T. G. MORTON, THE DISCOVERER
AND REVEALER OF SURGICAL ANES-
THESIA, AT LAST IN THE HALL
OF FAME—

A VINDICATION.

By S. ADOLPHUS KNOPF, M.D.,
NEW YORK.

THE MEDICAL RECORD has been good enough from time to time to publish the letters and comments referring to my humble efforts to get the name of William T. G. Morton, the most outstanding figure in American medicine, into the Hall of Fame. I am sure the whole medical profession is indebted to this periodical and the medical press of the entire country for the publicity given to the matter. THE MEDICAL RECORD may claim to have in no small degree helped in the election of Morton's name as one of the immortals among the great men of our country.

The outcome of the recent election must be gratifying to every American physician who is familiar with Morton's life, his struggles for recognition and the sad experience he was made to undergo by those who attacked him during life and those who up to this time wished to withhold the credit for his work. To any one who cares to know more about the sufferings and struggles poor Morton had to endure, I beg leave to recommend the book entitled "Trials of a Public Benefactor, as Illustrated in the Discovery of Etherization," by Nathan Payson Rice, published by Putney & Russell, 1859.

Our never to be forgotten Osler, with his keen sense of justice, gave us the result of his profound study of historical medicine concerning Morton's share in the discovery and promulgation of ether anesthesia in the following words: "William T. G. Morton was a new Prometheus who gave a gift to the world as rich as that of fire, the greatest single gift ever made to suffering humanity." And Professor Welch confirms the investigation of his life-long friend and in one of his recent letters to me says: "Surgical anesthesia has been America's greatest contribution to medicine and surgery and it would be a thousand pities not to have this recognized in the Hall of Fame. As only one name can be selected for this purpose, it is clear to me that this name should be Morton." Prof. Welch was one of the electors and his influence was no doubt an important factor in Morton's final triumph, for from the result of the election it is evident that the majority of the electors were of the same opinion as Professor Welch.

It will doubtlessly interest the readers of the MEDICAL RECORD to know the exact outcome of this year's election of America's immortals for the Hall of Fame. Of the 178 names voted on, the following seven were chosen: Samuel Langhorne Clemens (Mark Twain), who received 72 votes; James Buchanan Eads, the engineer, 51; Patrick Henry, statesman, 57; William Thomas Green Morton, discoverer of ether, 72; Augustus Saint-Gaudens, the sculptor, 67, and Roger Williams, the minister, a leader in liberal religion and founder of Providence, R. I., 66. The only woman who received enough votes to place her name

on the roll was Alice Freeman Palmer, the educator, who received 53 votes.

In view of the remarkable and pleasing result of the election to the Hall of Fame, it is regrettable that certain Southern lay papers, and particularly the *Atlanta Constitution*, should have lent their columns to an attack on the electors of the Hall of Fame because they had not honored the name of Dr. Crawford W. Long of Athens, Ga., to whom that paper states belongs the priority of the use of sulphuric ether as an anesthetic. The article was signed by Dr. Joseph Jacobs of Atlanta, who says: "Surely, this electorate of the University of New York, prior to their voting could have made little, if any, effort to weigh the evidence that so conclusively gives the honor of this unsurpassed achievement in medicine and surgery to Dr. Crawford Williamson Long of Jefferson and Athens, Ga."

The electors of the Hall of Fame, 102 in number, are men and women of national renown and certainly of irreproachable integrity. The officers of the Hall of Fame are Robert Underwood Johnson, Director (absent in service as Ambassador to Italy); Mrs. William Vanamee, Secretary and Acting Director. The entire electorate of the Hall of Fame is composed of actual or former university or college presidents, historians and professors of history, scientists, authors and editors, actual or former high public officials, actual or former justices—national or State, and men and women of affairs. The medical profession in this present election was represented by Major-General Leonard Wood, Professor William H. Welch and Drs. Charles H. and William J. Mayo. I hope the good and great general will forgive me for still claiming him as one of us.

It would be futile to recapitulate here, or even summarize, the controversies which were started during the lifetime of Morton by his adversaries and after his death by the heirs of Dr. Charles T. Jackson and Dr. Horace Wells of Hartford, Conn. (the latter also a claimant to priority of the invention of sulphuric ether as an anesthetic and an admirer of Crawford W. Long). Concerning the priority claims of Long and Jackson, I shall copy the following paragraphs from a letter Dr. J. Collins Warren, Moseley Professor of Surgery Emeritus, Harvard University, wrote me only recently in reference to this matter:

It is probable that Long performed three or four minor operations with primary anesthetic and then abandoned his claims. As Dr. Keen says, he is deserving of nothing but censure for not having appreciated the value of the agent. Regarding the claims of Jackson and his heirs, it cannot be too strongly insisted upon that Dr. Charles T. Jackson was very unwilling to have anything to do with the discovery at first. According to a letter by a son of one of those present at the first operation, Dr. J. C. Warren, it was not until he had attended an operation in Dr. Warren's father's office, to which he was invited and saw Morton give the ether most successfully, that Jackson came out the next day with an article in the newspapers claiming a share in the discovery. The heirs of Dr. Jackson now say that he was prevented from making the first public demonstration, that is to say, prevented from doing what Morton did at the Massachusetts General Hospital on October 16, 1846. The reason for Jackson's not doing this is given by the heirs as his being obliged to fill an important engagement to survey some mines in

Maryland, but they state that he had directed Morton what to do and how to do it and assumed all responsibility. According to this Jackson evidently thought the surveying of some mines more important than to give in person the first administration of sulphuric ether to a human being to prevent the pain and suffering which patients and surgeons had endured for centuries. Jackson's claim to have assumed all responsibility without himself administering the ether, would not have cleared Morton from guilt (homicide) had the patient not survived the experiment. Thus to Morton and not to Jackson belongs the honor of demonstrating to the world the greatest conquest of the age.

Regarding the responsibility for the result of the first demonstration of general anesthesia and the method of administering the ether, Dr. George W. Gay, Senior Surgeon of the Boston City Hospital and ex-President of the Massachusetts Medical Society, very pertinently says:

The man who gave the anesthetic upon that memorable occasion at the Massachusetts General Hospital was Dr. William Thomas Green Morton. He had experimented with sulphuric ether, had demonstrated its safety and efficiency and sought an opportunity to show its efficiency in general surgery. He assumed the sole responsibility of the demonstration. The results, whatever they might be, rested upon him. His enterprises, his enthusiasm and his courage brought success. Whatever suggestions or assistance he may have received from others, he was the man that made anesthesia a practical, everyday blessing to mankind.

Francis Darwin is indeed right when he says: "In science credit goes to the man who convinces the world, not to the man to whom the idea first occurs." (*Eugenics Review*, 1914.) Morton convinced the world, the credit is his.

There is perhaps no one in this country who has devoted more time to a painstaking investigation to sift the evidence of priority in this matter than Prof. William H. Welch of Baltimore. In answer to Dr. Jacobs' attack on the electors, and thus on Prof. Welch, who, as already stated, was one of them, I will quote the following paragraph from his anniversary address on "Ether Day," October 16, 1908:

The attendant circumstances were such as to make the operation performed on October 16, 1846, at the surgical amphitheatre of this hospital, by John Collins Warren, upon the patient, Gilbert Abbott, placed in the sleep of ether anesthesia by William Morton, the decisive event from which dates the first convincing public demonstration of surgical anesthesia, the continuous, orderly, historical development of the subject, and the promulgation to the world of the glad tidings of this conquest of pain. Had this demonstration or any subsequent one of like nature failed of success, it is improbable that we should have heard much of claims to the prior discovery of surgical anesthesia.

In defense of the other electors, if such would be deemed necessary, may I say that to judge from the correspondence I had with many of them, they have weighed the evidence of Morton's and all other claims carefully. Not one of these gentlemen committed himself beforehand, but each made me understand that he would investigate all the presented claims thoroughly and judge according to their merits. Dr. Joseph Jacobs is grievously wrong in ascribing to these electors superficiality in their work or partiality in their judgment. As evidence of the thoroughness and conscientiousness of the gentlemen may I be permitted to quote from a letter from Professor R. S. Woodward, the president of the Carnegie Institution of Washington, D. C., in which he writes in reply to the evi-

dences at my disposal I had sent him, including a facsimile of Oliver Wendell Holmes' letter, addressed to a Mr. Snell, which appeared in the *Illustrated Monthly Magazine*, of August, 1904:

I had already seen most of the data you furnish, but it will all be useful for reference in connection with the rather arduous tasks the electors of the Hall of Fame have assumed. It is a great pity that partisanship with respect to the merits of various candidates should be pushed so hard as it is. But data such as you have furnished serve to mitigate the severity of such partisanship. The facsimile of the letter of Oliver Wendell Holmes is very convincing in respect to the case of Morton.

Compared with the investigations of Dr. Welch in this matter, my own are trivial, yet in spite of numerous documents making claims for other names and letters of protests sent to me, some almost insulting because of my advocacy of Morton's name, I have come to the same conclusion as the distinguished dean of Johns Hopkins Medical School. The same opinion was strongly expressed by the great Oliver Wendell Holmes in the letter above referred to when he made an endeavor to settle once for all the then raging controversy. On April 2, 1893, he wrote as follows:

Dr. Bigelow had taken great interest in the alleged discovery. He had been present at the first capital operation performed under its influence, and was from the first the adviser and supporter of Dr. W. T. G. Morton, who had induced the surgeons of the hospital to make a trial of the means by which he proposed to work this new miracle. The discovery went all over the world like a conflagration. The only question was whether Morton got advice from Dr. Charles T. Jackson, the chemist, which entitled that gentleman to a share, greater or less, in the merit of the discovery. Later it was questioned whether he did not owe his first hint to Dr. Horace Wells of Hartford, Conn., which need not be disputed. Both these gentlemen deserve honorable mention in connection with the discovery, but I have never a moment hesitated in awarding the essential credit of the great achievement to Dr. Morton. This priceless gift to humanity went forth from the operating theatre of the Massachusetts General Hospital, and the man to whom the world owes it is Dr. William Thomas Green Morton.

The relative claims of the four contestants for the priority of the use of sulphuric ether as a means of general anesthesia in surgical operations, William T. G. Morton, Crawford W. Long, C. T. Jackson, and Horace Wells, are well summed up by Sir James Paget in the following words: "While Long waited and Wells turned back and Jackson was thinking, and those to whom they had talked were neither acting nor thinking, Morton, the practical man, went to work and worked resolutely. He gave ether successfully in severe surgical operations, he loudly proclaimed his deeds, and he compelled mankind to hear him." (Paget in *Nineteenth Century* for December 1879, "Escape from Pain.")

For the terms "anesthesia" and "anesthetic" we are indebted to Oliver Wendell Holmes who, as just stated, was a strong supporter of the claims of Dr. Morton as the one man to whom "the essential credit of the great achievement should be awarded."

In conclusion I may say that the fact that Morton, together with our most beloved Mark Twain, should have received more votes than any other candidate is a particularly good omen for the medical profession, and it is to be hoped that in future elections the names of our other great

pathfinders in medicine and surgery may not be forgotten. Such names as Ephraim McDowell, J. Marion Sims, Benjamin Rush, Walter Reed, and Lyman Spalding, the originator of the U. S. Pharmacopœia, all deserve a place among the immortals in America's Hall of Fame.

For the benefit of the present generation of physicians, I am very glad to be able to reproduce with this vindication not only the portrait of William Thomas Green Morton but also an excellent description of Morton's personality by a celebrated physician still living. It has recently been my privilege to visit the Nestor of American Surgeons, the venerable Dr. Stephen Smith, a physician who began his medical career before the epoch-making revelation of general anesthesia for capital operations. Those who have the rare good fortune to see Dr. Smith to-day, in his 98th year, will be surprised at the physical and mental vigor of this veteran. When I told him of my efforts to get recognition for Morton and to place his name in the Hall of Fame, he promised me his assistance. I begged him to give me the information in writ-

ing, and on July 30, 1920, he was good enough to send me what follows:

Regarding your inquiry about Dr. William T. G. Morton, I am very glad to forward you a few personal reminiscences. At the time of the controversy in Congress over the question of priority in the discovery of anesthesia I was editor of the *New York Journal of Medicine*. Dr. Morton called several times on me to discuss the situation and I had an opportunity to estimate the value of much of the evidence presented by the competitors. Dr. Morton was a man of pleasing personality, always faultlessly dressed, extremely courteous, and evidently controlled by a highly organized nervous system. It was due to his restless nervous activity that anesthesia was finally brought to a public test. His advocacy and practice of anesthesia in dentistry created a host of enemies, who sought his ruin. He met them with ever-renewed instances of success and finally with the famous operation of Professor Warren on the 16th of October, 1846, at the Massachusetts General Hospital. Even at this operation the enemies took advantage of a slight delay in the appearance of Dr. Morton to impress the large audience of Boston's most prominent physicians and surgeons that he did not dare face a real trial of his vaunted anesthetic. It was only at the conclusion of the operation, when Dr. Warren

spoke these words, heard around the world: "Gentlemen, this is no humbug," that they were silenced.

The portrait here reproduced I have been assured by Mrs. Theodore C. Otis, the only surviving daughter of Dr. Morton, is one of the best likenesses ever taken of her father.

William T. G. Morton was born in 1819, studied dentistry in Baltimore, and hoped by the practice of dentistry to gain the funds to study medicine. In due time he matriculated at Harvard as a medical student. He did not complete his medical education, but received from Harvard the honorary degree of M.D. for his great achievements in revealing and promulgating general surgical anesthesia. Morton died in 1868, a poor man, heart-broken because he failed to receive the recognition which was his due. Our great physician poet, the late Weir Mitchell, has immortalized the tragic life of Morton in the following touching lines, which he read on Oct. 16, 1896, at the Commemoration of the Fiftieth Anniversary of the First Public Demonstration of Surgical Anesthesia:

What angel bore the Christ-like gift inspired!
What love divine with noblest courage fired
One eager soul that paid in bitter tears
For the glad helping of unnumbered fears,
From the strange record of creation tore
The sentence sad, each sorrowing mother bore,
Struck from the roll of pangs one awful sum,
Made pain a dream, and suffering gently dumb!
Whatever triumph still shall hold the mind,
Whatever gift shall yet enrich mankind,
Ah! here, no hour shall strike through all the years,
No hour as sweet, as when hope, doubt and fears,
'Mid deepened stillness, watched one eager brain,
With God-like will, decree the Death of Pain.
How did we thank him? Ah! no joy-bells rang,
No peans greeted, and no poet sang,
No cannon thundered, from the guarded strand,
This mighty victory to a grateful land!
We took the gift, so humbly, simply given,
And coldly selfish—left our debt to Heaven.
How shall we thank him? Hush! a gladder hour
Has struck for him, a wiser, juster power
Shall know full well how fitly to reward
The generous soul that found the world so hard.
Oh! fruitful Mother—you, whose thronging states,
Shall deal not vainly with man's changing fates,
Of freeborn thought, or war's heroic deeds,
Much have your proud hands given, but naught exceeds
This Heaven-sent answer to the cry of prayer,
This priceless gift which all mankind may share.

In reviewing the history of Morton's life and labors, one finds indeed the justification of the inscription upon the monument erected at Mount Auburn Cemetery, Boston:

"Inventor and revealer of anesthetic inhalation, before whom in all time surgery was agony, and by whom pain in surgery was averted and annulled; since whom science has controlled pain."

16 WEST NINETY-FIFTH STREET.

Fragilitas Ossium with Blue Sclerotics.—Dr. Catharine Chisholm reports the case of a girl, aged 8 years, with typical blue sclerotics and traces of seven fractures, one in the right arm and the others in the legs. There was no otosclerosis, no peculiarity in the shape of the head, no family history, but the mother had suffered from dyspepsia during pregnancy. When first seen the girl showed physical and mental signs of thyroid deficiency. Great improvement followed the administration of thyroid, calcium, and cod-liver oil, together with massage and electricity. She is now bright, and can stand and walk with assistance.—*British Journal of Children's Diseases*.

VERTICAL DIPLOPIA LASTING EIGHTEEN YEARS RELIEVED BY OPERATION.

By J. A. KEARNEY, M.D.,

NEW YORK.

PROFESSOR OF OPHTHALMOLOGY, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL; OPHTHALMIC SURGEON, OUT-PATIENT DEPARTMENT GOUVERNEUR HOSPITAL OPHTHALMOLOGIST, OUT-PATIENT DEPARTMENT FRENCH HOSPITAL.

DIPLOPIA (double vision) in the majority of instances is traceable to dyscrasias, of which syphilis and tuberculosis are the most common, and to traumatism. Applicable therapeutic measures actively employed when a dyscrasia is found to be the likely cause usually give gratifying results, especially so when the cases are seen soon after double vision is noticed.

However, in some cases that are seen early and in most long-standing ones in which the specific therapeutic agents have failed to give results, and

Mrs. L. F., age twenty-seven, consulted me on August 17, 1920, and the following is the history of her case: When nine years old she fell from the fifth story of a building, was picked up unconscious and taken to the nearest hospital. She noticed when she recovered consciousness that objects appeared double. In order to

FIG. 1

in nearly all cases of traumatic origin other measures have to be considered for the relief of this most annoying symptom.

In the case reported below there was a partial paralysis of the inferior rectus muscle of the left eye producing a vertical diplopia, and a deformity of upward deviation of the eye as well, succeeding a fall from the fifth story of a building. It required twenty-two prism-diopters to place the objects on line horizontally.

Spectacles containing prisms necessary to correct this amount of diplopia would be unsightly and too heavy for constant wear, therefore impracticable. A frosted glass worn over one eye is most disfiguring. An advancement operation upon the rectus muscle of the left eye was suggested to the patient as a possible means to correct the diplopia and upward turning of the eye. This suggestion was accepted.

FIG. 2.

FIG. 3.

see objects singly she found that she was obliged to hold her head down on the right side (Figure 1).

It is eighteen years since the date of the accident and in all that time she has been holding her head in this same strained position. Her chief complaints were continual dull aching pains on the entire side of her head, in the neck muscles, and upper chest muscles on the

right side, also double vision when she changed the position of her head from that of down and to the right side. She had had nose bleed daily from the right nares for the past year.

The vision of the right eye is 20/20 and cannot be improved by lenses; the vision of the left eye is 20/40 corrected to 20/15 by a minus 2.00 diopter cylindrical lens placed at axis 165°.

When the head is turned down on the right side, the position that enables her to see objects singly, the eyes occupy similar situations in the palpebral fissures (Figure 1), but on placing the head in the normal position and looking straight ahead the left eye deviates upward 15° (Figure 2). The upper pupillary borders of both eyes reach the margin of the upper lids and are on line when the eyes are turned upward as far as possible. When the eyes look downward as far as possible the lower pupillary border of the right eye touches the margin of the right eyelid, but in the left eye the lower pupillary border is $2\frac{1}{2}$ m.m. from it. Lateral rotations are sufficient.

With the head in normal erect position and looking straight ahead a light at twenty feet distance was seen double, the dimmed light (false image) appeared down and to the left of the bright one, indicating a paralysis of the inferior rectus muscle of the left eye. A prism of 22 diopters base upward in front of the right eye was required to place the two lights on line horizontally and in this position they were about two and one-half inches apart.

The pupils were circular, equal, and promptly responsive to light stimuli. Media were clear and there were no untoward changes noted in the fundus of either eye.

The writer's advancement operation was done upon the inferior rectus muscle of the left eye on August 23, 1920, and the stitches were removed ten days later. On September 23 a photograph was taken (Figure 3). She now carries her head in the natural position. The deformity of upward deviation of the right eye is corrected; the eyes now occupy similar positions in the palpebral fissures when the head is erect and looking straight ahead. She is not troubled with double vision at this time with her head held in normal position and in order to produce a diplopia her head will have to be turned down and to the left side as far as it was held down and to the right side before the operation in order to maintain single vision. The left eye may be turned upward and downward to the same extent as the right eye. Diplopia occurs when the eye is moved downward from 5 to 10° from the straight position. She has had no bleeding from the nose since the operation. The unbearable aching pains that existed in the side of her head, neck muscles, and upper chest muscles on the right side before the operation are there no more. She is now wearing spectacles for her visual correction only.

127 WEST FIFTY-EIGHTH STREET.

ROUND CELL SARCOMA OF THE NASAL VESTIBULE.*

By GEORGE D. WOLF, M.D.

NEW YORK.

WHILE the profession, as well as the public, has been fully aroused to regard pelvic, gastric, and breast tumors with suspicion, tumors of the nose and sinuses do not receive their proper attention. Whether this relative lack of attention is due to the actual rarity of malignant neoplasms in these locations or to the paucity of reported cases, is conjectural. However, the outstanding feature about this problem is the infrequency with which specimens removed by the otorhinologist are subjected to microscopic examination. It is indeed regrettable that most nose and throat surgery is done at

*Presented at the New York Academy of Medicine, Section on Rhinology and Laryngology, October 27, 1920.

the office, or in the O. P. D. of hospitals, where facilities are not as adequate as one might wish for under ideal conditions. The patient, too, has come to regard these nose operations as ordinary and everyday procedures, and cannot always con-

FIG. 1.—Showing glandular enlargement.

ceive the necessity of additional expense for the microscopic examination of pathological material. Cooperation with the x-ray man and bacteriologist is also lacking.

Manifestly the practice of doing most of the otolaryngologic surgery in the office and the lack of emphasis on the part of the surgeon as regards microscopic examination of removed tissue do not enhance the progress of this specialty. The frequency with which so-called polypi and enlarged turbinates are snared off without thorough previous

FIG. 2.

examination, is another factor which adds to the disrespect, or disregard (if one may so express it), in which intranasal operations are generally held.

Occasionally a so-called polyp is removed after a hasty and incomplete previous examination, only to

have the operating surgeon discover soon afterward that the benign polyp, or the congested turbinate, has recurred, and is infiltrating adjacent tissue. Higgins' mentions such an experience.

It is for this reason, and not so much because of the rarity of the condition, that the following case is reported:

A. J. G., male, 47 years, U. S., painter. Came to the Harlem Hospital O. P. D. on Aug. 27, complaining that for the past three or four months he had noticed a gradual obstruction of his left nose, becoming complete within the past few days. He also had a disagreeable taste in his mouth, and a malodorous discharge from his nose. For the past week he had a severe left-sided frontal headache. There was no history of epistaxis or loss of weight.

Family history: Father died at 54 from heart failure; mother, 73, alive and well; one brother died at 14 months from hydrocephalus; two sisters and one brother alive and well. No history of malignancy in the family.

Past history: Ordinary diseases of childhood; pneumonia at 14, erysipelas of the leg at 33 years of age. He has had a chronic, persistent, hacking cough, which he dates back to his attack of pneumonia. Had an intranasal operation about 30 years ago, after having been

Blood: Wassermann, negative. Hgb., 75 per cent.; R. B. C., 3,480,000; W. B. C., 13,600; Polys., 77 per cent; Lymphocytes, 23 per cent.

Urine, negative.

Dr. Wm. H. Stewart reports the following roentgenographic findings: "The air sinuses of the entire left side show involvement of some process, which has almost completely obliterated the cavities. The character of the shadows would seem to indicate some solid body more than a fluid. The lower part of the left antrum still contains air. The left side of the nose is completely blocked, and we are unable to map out any outline of the turbinates. I am suspicious that there is also some involvement of the ethmoidals on the right side. They lack the clear detail one would expect with normal cells. Chest, negative."

The suspicion of malignancy was aroused when slight manipulation of the growth by the probe resulted in profuse hemorrhage and the patient had to be sent home and advised to report again. When he presented himself the second time, within a few days, his submaxillary glands were found to be enlarged. (Fig. 1.)

A specimen was removed from nose and submitted to Dr. T. A. Gonzales, who reported as follows: "Several small pieces of tissue, which on cut section show a homogeneous, yellowish white surface. Nothing of interest grossly. Microscopic section shows area of small, slightly irregularly shaped nuclei. The cells have a small amount of plasma and the nuclei are rich in chromatin. In some spots there are numerous mitotic figures showing active growth. The cells are slightly larger than the ordinary lymph cells. The whole tumor is made up of these cells held together by a fine, fibrous stroma, which in some places is hardly discernible. Here and there a new-formed blood vessel is made out. There is no regular arrangement of cells. Diagnosis: Round cell sarcoma." (Fig. 3.)

Shortly after the removal of the pieces, the patient ceased to visit the clinic. When visited at his home, the patient stated that he felt much better and was able to breathe through the obstructed side, and therefore did not care to lose any more time from his work. Only by intimating to him the gravity of the ailment was he induced to return for observation and treatment. He was advised to submit to radium, and was referred to the Memorial Hospital on Dr. Janeway's service, where he received two exposures on October 11 and 12, respectively.

Comment:—The etiological factor in this case is, of course, obscure. Trauma and chronic inflammation are still the only factors which are usually given. In this case there is some slight evidence of injury. Whether the patient at one time suffered from any nasal condition, such as inflammation or other neoplasms, cannot be established.

Whether polypi or fibrous tumors of the nose ever undergo degeneration has not been fully proven as yet.

Clark,² in reviewing 147 cases of nasal polypi, states that it is extremely rare for polypi to undergo malignant degeneration, as he never saw a case.

Watson,³ on the other hand, in a study of the records of 150 cases of sarcoma of the nasal passages, found 24 of the patients to have had polypi before.

The same author, in discussing the age of recurrence among the 150 cases, found in the First decade, 4; Second decade, 18; Third decade, 20; Fourth decade, 20; Fifth decade, 26; Sixth decade, 18; Seventh decade, 12; Eighth decade, 3.

These occur in the male more than in the female.

Order of frequency: Round cell sarcoma, fibrosarcoma, myxosarcoma, spindle cell sarcoma, melanotic sarcoma, adenosarcoma, and lymphosarcoma.

Prognosis: Even with an early diagnosis and treatment, opinions seem to vary on this point. Ballinger⁴ considers the condition as grave. Wat-

FIG. 3.

hit by a baseball bat. Venereal history denied. He was a heavy drinker until about a year ago, but drinks very moderately since. Does not smoke or chew. Eats and sleeps well.

He cannot recall any particular trauma to his nose, except the accident mentioned thirty years ago, and a fight two years ago, resulting in a swelling of the left cheek and echymosis of the eye on the same side. On Dec. 19, 1919, he fell off a scaffold, causing a fracture of two ribs. He was unconscious after the accident, and cannot state whether his nose was injured or not.

Physical examination: Poorly nourished; skin of pasty appearance, and complexion sallow; eyes present slight exophthalmos, Dalrymple, Graefe, and Stellwag signs are present; double dacryocystitis, but more marked on left side; fundi, negative. Nose-septum markedly deviated to right and adherent to the inferior turbinate of that side. In the left side none of the usual landmarks are to be made out. The whole naris is filled with an irregular mass, pinkish in color, which is soft in consistency. A retropariaryngeal examination showed this mass to fill the posterior naris. There is tenderness over the left frontal sinus and Ewing's sign is present. Pressure elicits but slight tenderness. The submaxillary and cervical glands are not palpable. Pulse 110, regular and of good quality. Weight 127 pounds.

son¹ gives the average duration of life as that of two years. Sonnensheim² thinks the future of radium treatment is very bright.

None of those who have studied this condition seem to be any too optimistic and it is quite safe to say, if not the patient himself, the family, at least, ought to be told about the seriousness of the condition.

Treatment: Either surgery followed by radium, or the latter alone, is to be resorted to. In looking over the literature on the subject, it is rather hard to decide what to urge the patient to do.

At a recent meeting of the Royal Society of Medicine,³ the question as to treatment was raised, and there was equal enthusiasm as to surgery and radium.

Conclusions.—1. Whenever feasible, specimens removed from the nose should be submitted to the pathologist. This will at times prove life saving, and will help greatly in the study of the pathological processes of the nose.

2. In every case of epistaxis with evidence of growth, or when a growth bleeds profusely on slight manipulation, it is absolutely imperative to have a specimen submitted to pathologist.

3. Since chronic inflammation and benign growths of the nose are the only etiologic factors known to cause malignancy, the patient must be made to understand the necessity of thorough removal of existent growths, as well as the eradication of any inflammatory condition.

4. Finally, it would be an interesting study to investigate all the malignant growths of the submaxillary and cervical glands to see what proportion, if any, of those have had their origin in the nasal chambers.

TYPES OF MAMMALS.

WITH NOTES ON HYBRIDS, DISEASES, ALBINISM, AND OTHER CONDITIONS EQUALLY APPLICABLE TO MAN.

BY R. W. SHUFELDT, M.D., C.M.Z.S. etc.

WASHINGTON, D. C.

In a former article, published in the *MEDICAL RECORD* of September 11 and October 23, 1920, I made an attempt to point out what is meant by a species in zoology in general and in mammalogy in particular. Now in addition to a species we often hear of such things as *types* being spoken of, this or that mammal is "typical"—it is a *type*. In reality a type is hardly to be considered any more a fixed fact in nature than a species is to be so regarded. Not so very long ago, naturalists, and nearly everybody else, believed that all "species" and all "types"—as they were in those days understood—were in-

dependent creations. A racoon, a cougar, or any other mammal, for example, was a lineal descendant of its respective ancestors of the Noachian menagerie which, as the fable goes, were cooped up in the Ark. More than that, it was even considered to be practically the unchanged counterpart of the original racoon or the original cougar of its pristine ancestors that roamed in the fabled forests in the mythical garden of Eden. In other words, species and types for all times had been miraculously created in the beginning of life in the world, and their present-day descendants were in no particular different from them. In the days to which reference is made, naturalists all belonged to the old-fashioned school of "species-makers." When a mammal "new to science," for example, was "discovered," the much-to-be-envied mammalogist set to work at once to publish somewhere, in some eminently respectable "scientific medium" or other, its exact *specific characters*. In a similar manner the world of nature was ransacked to "discover" new genera, new families, and representatives of any of the higher groups.

Following out this idea, when a new species had been discovered and its specific characters duly an-

nounced and recorded, every subsequent "specimen" met with that presented characters similar to the *type specimen*, was considered to be of the same species, and so on for the other groups. Such specimens were regarded as "typical specimens." After a while, however, as material accumulated, naturalists came to realize that all species were not completely typical. Some varied. These variations were designated in the books in a number of ways, and were often spoken of and written about as being *subtypical*, while those that departed still more, either one way or the other, from the classical and stereotyped specific definition were considered to be "aberrant forms."

The history of all this part of the growth of zoological machinery, and the blind efforts of the naturalists of those days to adjust their ideas with what really existed in the natural world, is extremely interesting; but the limitations of space forbid its being gone into to any extent here.

Years after all this, the complete establishment of the law of organic evolution revolutionized the en-

tire system, and what the older naturalists understood by a "species," a "type," a "subtypical specimen," an "aberrant species," and especially by "types of structure," was very differently regarded. According to the aforesaid antiquated theory, when

FIG. 2.—An Albino woodchuck. Captured in Virginia. Photo from life by the author.

any animal was looked at in the light of representing a certain recognized *type of structure*, it was with the idea that that particular living form was *fixed in structure*, had been cast in some particular mold, the pattern of which was, always had been, and always would be immutable absolutely. Types of structure are now no longer so regarded by naturalists or by any one else who is familiar with the main factors of the law of descent of plants and animals. Many, indeed, are now the recognized types of structure. There is, for example, such a thing as the general *back-boned* or *vertebrate type of structure*, by which is meant that the general morphology of any vertebrate animal, in its entirety, stands for a structural type. In assuming this, however, it must be definitely understood that such a type is not and never has been fixed, but simply represents a single modification of a common plan of organization, the evolution of which, since its pristine establishment, has resulted in a production of all other vertebrate forms likewise to be regarded as types, as those of fishes, batrachians, birds, and mammals. Keeping this clearly in mind, it becomes evident that any conventional collection of animal forms, constituting a zoological group in the animal kingdom, is, in reality, a *type of structure*, that, according to the period of its existence, is to be regarded as possessing a more special or a more general significance.

New types are produced by the descendants of pre-existing forms having become, to an appreciable degree, structurally modified away from the morphological organization of those ancestors; in which case, in the resulting progeny, any particular individual or specimen is typical of the more recent species, and the new species becomes typical of its genus, and so on.

This can only occur, however, when sufficient time has elapsed for the evolutionary change to have come about. These changes have been going on ever since living forms have appeared upon the earth, and so, throughout all time, there has been a succession of specific, generic, and other group-

types of structure; this is exactly what is taking place in nature in the present age of the world's history.

To illustrate, let us say that millions of years ago there existed upon the earth a generalized, amphibious type—an animal possessing a certain type of structure as above defined. It would be the common ancestor of its future descendants, presuming, as we do, that from such a stock an innumerable progeny descended. As the ages wore on, from this common, primeval stock a twin divergence became apparent; two groups were forming. The differences were so slight at first as to be scarcely appreciable; but in due course, however, an individual of the one group became specifically different from an individual of the other—that is to say, two distinct species had come into existence. As the ages passed by, the divergence thus established became markedly more and more evident, and genera, families, and all the other conventional groups came into existence, resulting at last in the two distinct classes, namely the *Amphibia* and the *Mammalia*. Reasoning from this presumption and the facts—as far as they are known to us in this case—it may be said that the *type of a mammal* is the one which has become most highly specialized and, structurally, the farthest removed from the amphibian type. It may be that man, the species *Homo sapiens*, represents just such a type. Confusion in such matters has been brought into this question by some naturalists claiming that the type of mammal, for example, is seen in the primitive stock from which, in time, all mammals have been derived; and in this case, man would be considered to be the least typical of all mammals known, in as much as he possesses an organization the farthest removed from the original and common ancestor. Judging from man's anatomy to-day, we would never for an instant imagine that he, as a mammal, had been derived from an early amphibious progenitor. It is the exception to place this construction upon the meaning and use of the word type. There have been terms proposed by several writers to obviate this confusion; thus, by the word *teletype* we supplant the word "type" as it was used in its most common sense. Then, selecting the word *prototype*, we have a word which, in its wider meaning, indicates any

FIG. 3.—Right lateral view of the skull of a black bear. Collected in Virginia. The point of entrance of the Winchester ball that killed him is seen on the side of the cranium. Much reduced. Photographed by the author.

form (or forms if used in the plural) from whence, through evolution, any teletype, in any specified line of descent, has been derived. By the employment of their adjectives, we may then say that, according to Cope, the *Creodonts* are prototypic of the

now existing *Insectivora* and *Carnivora*, and that these two latter groups are teleotypic of the former. And again, we see a highly specialized teleotype in the modern horse that has been derived from its prototypic ancestor, the *Eohippus* of the Eocene

FIG. 4.—Left lateral views of the skulls of adult specimens of the ring-tailed racoon (*Bassariscus*) and its allies. Natural size. From photographs by the author, introduced to show the elegant dentition in these animals.

basin, the latter being teleotypic of the stock from which it, in turn, was derived; and so, in general, any species is prototypic of those from which it is directly descended and teleotypic in its own genus. All species are teleotypic of the genera to which they severally belong, the genera of their respective families, and the families of their several orders. Evidently, the converse of this is likewise true, and equally true when applied to the Class or any of the higher groups.

Furthermore, it will be seen that we have no prototypes or prototypic species in existence; they are all teleotypic of their progenitors, yet, at the same time, will become prototypic of their descendants in the ages to come.

Other authors have used still other terms to express their meaning in regard to what a species is, what a type indicates, and other questions which have been touched upon in the foregoing paragraphs; but it is believed that what has been set forth will render all these matters sufficiently clear without any further explanation.

Leaving any extended consideration of this subject, then, to those who desire to pursue it in their reading of the works of others, it will be more to our purpose here to make a brief, preliminary survey of the habits of mammals in general.

By the study of the habits of mammals is meant a scientific consideration of their behavior in a state of nature, and, incidentally, how this behavior is affected by their being kept in a state of captivity, and by other circumstances. Such observations are extended to include both sexes and the young from time of birth. It leads us to investigate, as far as possible, their habits during the day as well as during the night-time; their feeding-habits and courtships; their battles and their modes of amusing themselves; the various ways in which they care for their young, and the question whether they are in the habit of performing any special migrations. Indeed, although the study of habits is generally considered to be a more restricted field than the study of the entire life history of a mammal, it nevertheless constitutes one of great interest and decided importance; though, from a biological standpoint, by no means as important as the scientific consideration of their geographical distribution, their morphology, and their classification.

When it can be done with advantage, the study of the habits of various mammals should be made comparative, that is, the behavior of one species contrasted with that of another and under similar and all circumstances. This applies more particularly to the allied species and genera, as nothing would be gained by contrasting the habits of a squirrel with those of a caribou; whereas to compare the habits of a muskrat with those of a beaver, or those of a woodchuck with those of a "prairie-dog," would be interesting as well as important.

Some animals have the habit of hibernating during the winter time, especially in northern climates, as some of the bears; while others are as active during that severe season as they are at any other time of the year, for instance the wolves and the *Cervidæ*. The entire question of the habit of hibernation is one of marked interest. Most animals, when they enter into this state, lapse into a torpid condition and seek complete seclusion. There are, however, exceptions to this, as among the bats, where large numbers of the same species often hibernate together. They do this apparently to insure greater warmth, and perhaps, too, they may be prompted by the desire to secure sociability. Moreover, cold is

FIG. 5.—Right lateral view of the skull of a badger. Prepared, collected and photographed by the author in New Mexico. Nearly natural size.

not the sole cause of inducing a mammal to hibernate; it may be that it has been deprived of the usual supply of food gathered during the previous season. Most species become very fat during the several weeks just prior to entering upon the long sleep in

their winter quarters. Some are easily aroused at any time during this period of hibernation, others less so; while some pass into a complete state of torpidity. So we must not confuse the mere fact of a mammal's hibernating with its state of torpidity or condition of profound sleep during that seclusion. The time of appearing, when spring comes again, varies with different species of mammals; but, as a rule, they make their appearance early, and are generally very lean and very hungry. Bears are extremely dangerous at these times.

Among the most interesting habits of mammals are those of their various modes of securing their food and their feeding. Some subsist almost entirely upon a strictly vegetable diet, and quietly browse in the fields or in the forests, as many of the deer and the *Bovidæ*. Others, such as the carnivores, destroy and consume other animals upon which they prey; while still others live upon a mixed animal and vegetable diet. It then becomes of importance to know how often and when the various species of mammals feed; and, in the case of the herbivorous forms, what plants and trees they live upon and which ones they reject. Many of the rodents are exclusive gnawers and subsist upon nuts, roots, and the bark of certain trees. Not a few of the *Sciuridæ*, however, are carnivorous, as various squirrels will eat flesh with avidity, and muskrats devour mussels.

The feeding of the strictly carnivorous mammals especially attracts our attention, for it so frequently involves the matter of the chase and capture of other animals. This makes incident and history, as the accounts of such captures vary greatly in the circumstances attending them. It arouses very little or no excitement simply to watch an antelope quietly browse out on the prairie; while it is an entirely different affair to observe a pack of hungry wolves start in and run that antelope down. That is exciting and arouses similar instincts in ourselves. Finally, among the list of almost innumerable ways by means of which mammals secure their food, we have other instances where they dive beneath the water for it, as an otter does after fish. As a matter of fact, the feeding habits of mammals in general would, if given, fill many a volume, and those in particular of the game mammals of this country would make a volume of very considerable proportions.

Coming to the matter of the courtship of mammals—their mating—we enter at once upon another field more than full of interest to any one evincing a desire to be informed upon the life-histories of this important group. Their habits in this particular are as varied as their feeding habits, and far more remarkable. Still, in truth, one merges indistinguishably at certain points into the other; for some mammals after mating feed their dams; both usually feed their progeny, and the latter is the outcome of their courtship and mating. So it is that all goes toward making up the life-history of the species.

But apart from these facts, the study of the mating of mammals *per se* is one of the most entertaining and instructive chapters in their history. It calls upon us to examine into the real, structural, and mental differences existing in the sexes; it requires us to study and contemplate upon the times

of the year when the instinct moves them to seek each other to enter upon this delightful episode in their lives; it invites investigation of the changes, so multifarious in character, which take place in the sexes at these eventful times; it impels us to note the various sexual characters of the males and the females, to study the action in their modes of copulation and reproduction, and, finally, to examine into what their young are like, how they are cared for by their parents, and the various stages of their subsequent development. In all these matters, mammals of different genera—and sometimes species—differ in a multitude of particulars. As a single example, what can be more dissimilar than the mating, and all that it entails, of a wapiti and an opossum? a porpoise and a porcupine? yet the end to be attained is in reality identical. The acts of the drama in the common play follow the same sequence—first to observe, then to seek, next to attract, to be followed by an excitation of emotions, an impulse to drive off and give battle to all rivals, succeeded by the reward in conjugal union, and, finally, the appearance and development of the progeny. It is a charming life-chapter when, from beginning to end, its course runs smooth; but lackaday! as it is with men, so it often is with minks and marmots, a full measure of misery is only too frequently meted out to them when the wounded ones are called upon to quaff their cup of bitterness. Such coincidences are met with many, many times, and offer us abundant opportunity for contemplation. It may be that the life of a female cougar will be taken very soon after she has given birth to a fine litter of cubs. This leaves the male in a sorry plight, and it is rare that we come to know what he does under the circumstances. Again, it is a well-known fact that rival deer, in battling for a favorite spouse, not infrequently lock antlers so completely that their disengagement becomes impossible, and both animals perish by starvation.

We know a good deal about the habits of animals, but it is extraordinary how little real knowledge we have acquired of the habits of the most abundant species in this country. The thirst for species-making seems to have completely filled the minds of the majority of our mammalogists, and little or no attention is paid to their life-histories, including their every-day habits and their morphology.

Turning to the question of hybrids, we find but very little literature, comparatively speaking, in this department of mammalogy. Zoölogists nevertheless have paid not a little attention to it, and it has been more or less studied by them. But there has been no exhaustive work published, giving a full account of all the cases known of the production of hybrids among the ferine mammals of this country. The late Judge Caton, in his well-known volume on "The Antelope and Deer of America," left us much of value on this subject as it occurs among the *Cervidæ*, and reference will be made to it further on. Then there is quite a literature dealing with the hybridization of the bison with domestic cattle; for it has been encouraged in captivity of the former with the view of furthering man's interests in the matter of trade. Many hybrids have been produced among the coyotes and camp dogs about the Indian camps in Dakota and elsewhere. To a limited extent, these have been studied, but very little has

been written about them. They are known as half-breeds, cross-breeds, or mongrels. In the case of mammals, hybrids are the progeny resulting from the crossing of different subspecies, species, and genera. When the zoölogical difference is great, however, the production of hybrids is quite rare. It is more common among birds than among mammals. It is very seldom observed when the parents represent different zoölogical families, though the writer has seen a hybrid result from the crossing of a guinea-hen and a fowl; it presented distinct intermediate characters. Most often hybrids are produced when the cross-breeding takes place between the sexes representing the subspecies of two different species. Such hybrids are more common than it is generally supposed. In mammals, as a whole, such progeny is probably commonest among men and among the domestic *Equidae*. With respect to the latter, we see them in mules, jackasses, and their kind. Foxes and dogs have crossed successfully, and this is an instance where the parents belong to different genera: *Vulpes* and *Canis*. As a rule, however, when the parents are thus far removed, fertility forms the exception.

When hybrids are the result of the crossing of distinct species, such hybrids are usually infertile—that is, *inter se*; while they may propagate by again crossing with the pure breed of either parent.

Generally, the fate of hybrids, so far as mammals are concerned, is to die out; but through artificial and forced cross-breeding, they may be indefinitely produced. Often very handsome creatures are the results of such crossing, as, for example, the various "breeds" of domestic cats and dogs. Such animals must not be confused with true zoölogical subspecies as we find in nature.

Ferine mammals, again, are subject to many diseases and injuries. In very numerous instances, these are identical with the same diseases and injuries to which man is heir. As a matter of fact, all those accidents which are the result of traumatism—or the class known as surgical injuries—are identical. The processes of healing in the case of fracture, of gunshot wounds and similar injuries, are precisely the same in a mouse as they are in a man or any other mammal. With respect to many of the typical diseases, it goes without the saying that their causes, effects, and results are the same throughout the mammalian orders, man included. Still, there are a number of diseases that the mammals below man are subject to, to which he is not, and *vice versa*; but there is always a reason for this, whether we have ever discovered that reason in any particular case or not. It is nevertheless quite clear why a whale should never suffer from smallpox, nor a man contract a fracture of the epipubic bones; for, in the first instance, that huge marine mammal is never submitted to the contagion of smallpox, and in the second, men do not possess the epipubic bones in their skeletons, as these are found only among the marsupials.

When living in a state of nature, most ferine mammals—when they do not die of old age—probably, in the vast majority of instances, succumb to various kinds of traumatic injuries and accidents. Many are often drowned; many kill each other; man destroys immense numbers of them in traps and with powder and ball; some are destroyed through

various accidents, and starvation and other causes claim their quota. They are subject to different diseases of the organs of special sense—the eyes, ears, and nose. Many are victims of parasites of not a few species. Some die from poisons at the hands of man; while, in rare incidents, lightning, sunstroke, earthquake, volcanic eruptions and other natural phenomena have destroyed a comparative few, and prairie fires have, in many cases, wiped out others. Rattlesnake bite has been the cause of death in other cases; and birds of prey destroy thousands upon thousands of the smaller and medium-sized species. They are subject to paralyses resulting from various causes, and those troubles terminate often fatally. Skin diseases are not uncommon among them, and the writer once shot a coyote in New Mexico that had lost nearly all of its fur from some form of mange or other. Malformations of various characters destroy others, as in those cases where the teeth of rabbits and other rodents, from non-approximation of their cutting edges, grow and curve inwards until, piercing the brain, they kill the animal so afflicted. Still others die when giving birth to their young, while among the latter as many monstrosities are born as occur in our own species. I have seen a young antelope (*Antilocapra americana*) with two perfect heads; a cat with no legs, and various grades of the "Siamese-twin" class. When born blind, mammals in nature die of a natural consequence, and congenital deafness very much diminishes their chances for longevity. Diseases of the generative and urinary systems seem to be extremely rare; but this is probably due to the fact that they lead normal lives, which man most emphatically does not, and so suffers the consequences.

But in reality we know comparatively little of the question of vital statistics among wild animals, and thousands of observed cases have never been reported and published. Still, a great number of the diseases and injuries to which they are subject are known to us through our general knowledge of pathology, and our observations upon diseased and injured animals in a state of domestication.

Mammals, including man, are subject to other conditions that must in no way be confused with diseased or pathological ones. Reference is here made to those peculiar and abnormal states known as *albinism* and *melanism*. The first is also sometimes termed leucopathy and leucism, which mean exactly the same thing. An albinistic individual is very generally called an *albino*, and albinos occur not only among mammals but likewise in plants. Comparatively speaking, it is a somewhat rare occurrence; but when found, and it is complete, it is known to depend on an absence of the coloring matter in the skin. This coloring matter consists in minute particles, which usually occur in the lowest layer of the outer skin or epidermis. A typical albino has eyes that are entirely of a bright pink color and a skin which is quite white. This state of things, however, may be only partial, the coloring matter not being entirely absent. Albinos of this class may not have pink eyes, and the shade of the skin may be almost normal in tint. Some others are *pied* or *piebald*, as we frequently notice to be the case in certain horses. Indeed, we may have almost every possible grade and degree of this curious con-

dition. Darwin has shown that albinism may be strongly inherited, and cites the cases of white mice and rats as examples. Some mammals seem to be more subject to it than others; but it must always be distinguished from the normal state of a white pelage as we see it in the polar bear and other animals. Nearly all naturalists appear to consider an albino as a "sport" or "freak" of nature; but I have never considered it so, as I do not believe such things as sports and freaks occur in nature, and I am inclined to regard it in the light of our lack of knowledge of the real cause. Every state of things—and albinism is no exception—is due to some *definite cause* or other, however obscure and hidden that cause may be. We have not discovered as yet the reason why the particles of coloring matter are absent in the skin of some individuals and not in others, even when those individuals may belong to the same litter. Albinism may occur in any species of mammals, and even in the writer's own personal experience it has been noted in several species of deer, in the muskrat, the woodchuck, various species of squirrels, in the beaver, and others too numerous to mention.

In *melanism*, which is the opposite state of things to albinism, the pelage of a mammal has developed or deposited in it an abnormal amount of a black or dark pigmentary matter. The arboreal squirrels seem to be particularly subject to this, and it is no more a pathological condition than is the albino state. In fact, a melanistic mammal is quite as healthy and vigorous as the one normally colored. Agreeing with albinism, it, too, may become inherited; but the disposition to do so does not seem to be as strong. This state, also called *erythrism*, is best seen in the black rat (*Mus rattus*), an animal in which this condition appears to be permanent, but which originated in melanistic individuals of the common roof-rat or white-bellied rat (*Mus torum*), and has since become hereditary. One of the best cases of partial melanism ever seen by me was that of an antelope (*Antilocapra americana*) on the plains in Wyoming near Fort Fetterman in the latter part of the '70's. It was a buck and possessed an entirely black head. Before I had an opportunity to dismount from my horse and fire at it, it was speeding away at its best, leading some eight or nine others. Its course was at right angles to the barrel of my carbine as I brought it to my shoulder; but upon firing I held too far back, and, as chance would have it, killed the doe immediately in the rear of the animal I more than anxiously hoped to secure.

Possibly I may have been mistaken, but it seemed to me at the time that that antelope was an unusually large one. It may, however, have been owing to the fact that it certainly would have been a great prize had I bagged the animal, and all prizes, before taken, are deceptive and appear to be greater than they really are. Still, among mammals, we not infrequently meet with unusually large individuals, and, in some cases, those which are undersized. This is the case in our own species where we have, as is well known, both giants and dwarfs. As a matter of fact, it is the exception to meet with any two adult specimens that measure the same in all particulars. For example, we often hear of unusually big moose being killed, and investigation

proves that the records have been correctly given. In the case of the common red fox, this fact is so notorious that hunters have applied the term "a Jumbo fox" to the markedly over-sized individuals. From personal observation I can say that the sub-melanistic specimens of the muskrat are larger than the ordinary and normally colored ones—a fact that I have ascertained by actual measurements. Especially favorable environments and a great abundance of the very best food all the year round doubtless have much to do with this in the majority of cases; and the converse also holds true, for, where animals exist amidst disadvantageous surroundings, with scant and unsuitable food, they become dwarfed. In other instances, giants and dwarfs appear where no such conditions seem to account for them or to have had any influence. These individuals, it is claimed by some, are "sports" or "freaks of nature," an explanation I place no store by, as has been stated in a former paragraph in this article. Variations in size naturally account for corresponding variations in weight, though the two conditions are not exactly complementary ones, as two animals may measure precisely the same in all particulars, and yet one be heavier than the other, owing to its being stouter, or possessing a weightier skeleton, denser pelage, and so on. We should be very careful how we regard these variations in the matter of publishing descriptions of new subspecies. More attention should be paid to the *extremes* in these particulars, and these be taken and published, and averages estimated as frequently as possible on all the data that can be gathered. But the exercise of such care and presentation of statistics will do away with a great deal of trouble in the matter of synonymy for the naturalists of the future.

What has just been said applies equally to the questions of form and color. No two mammals of the same species or subspecies are exactly alike in these particulars, and sometimes the variations are strikingly marked. This applies to their entire anatomy or morphology. It is best to be observed when the opportunity is offered to make exact comparisons in the case of a very large number of individuals of the same species. They vary remarkably sometimes, and these variations are often very noticeable in the skulls and other parts of the skeletons. Not a few accounts of this kind have been published from time to time and with figures showing the differences. Take the heads of deer for example, how they vary sometimes, and this quite apart from the variations to be observed in their antlers. They possess different faces and different expressions. So it is, too, with their general forms.

Some years ago I published the enlarged views of the skulls of two Yellow-headed Blackbirds (*Xanthocephalus xanthocephalus*), and these were so unlike that one would suppose they had belonged to birds representing different genera. Still, their main specific characters corresponded, and they were both typically icterine!

When mammals become extremely old, great changes sometimes follow in their general morphology; but these are simply the changes that attach to senility in any species. It may be seen in our own species—not only in the appearances of the face, head and body, including the limbs and other

topographical features, but in all the deeper parts, and especially in the skeleton. It is extremely interesting to compare the skull of a very old person with one of middle life of the same sex. Similar changes occur throughout all animals in nature, and it is often unfortunate that some untrained biologist, in describing new subspecies of mammals, regards these individual skeletal differences as possessing subspecific value and weight, when, in numerous instances, they are simply of an individual nature, and vanish, in so far as they are of any use taxonomically, in the light of an examination of a sufficient amount of material. So it goes, too, in the matter of color. We meet with both light and dark-colored specimens, and that quite apart from any taint of any character of either albinism or melanism. It becomes a matter of shade and variation in color areas. Sometimes this is quite noticeable among skunks, weasels, and other representatives of the *Mustelidæ*. Climate, food, life, and environment doubtless have their influence here as they have in the matters of form and weight. Sometimes mammals possessing a pure white pelage become stained—more or less permanently so—with adventitious matter of various kinds; such staining must be carefully noted and a discrimination made between it and the normal pelage.

In some instances certain soils, especially the clayey ones, are liable to produce such effects where white or light-colored mammals habitually live in the regions where the ground is of such a character. Out on the American prairies I have observed specimens of badgers, which permanently exhibited a shade of buffy color due to the staining with the yellowish-red clay wherein they had excavated their burrows; and other cases might be cited. In their studies of mammals, students should always exercise special care to take all these matters into consideration and attach the true significance to them, particularly in regard to the questions of variations in weight, size, form (including all anatomical parts), color, and the other characters which have been touched upon in this article.

CANCER DEATH RATE IN NEW YORK CITY DURING 1920.

By L. DUNCAN BULKLEY, A.M., M.D.

SENIOR PHYSICIAN TO THE NEW YORK SKIN AND CANCER HOSPITAL, ETC.

It seems very appropriate that the MEDICAL RECORD should keep its readers acquainted with matters relating to the life and health of the community. For several years past, therefore, I have made a study of cancer mortality in New York City and elsewhere, with a view of awakening the serious attention of the Medical portion of the profession, especially, in the hopes of securing generally better measures to control the morbidity and mortality of cancer than have prevailed during the past twenty years, at least. For, as has been repeatedly shown, the mortality of tuberculosis has been reduced by diligent medical attention some 30 per cent. during this period, whereas that of cancer has risen by almost exactly the same 30 per cent. in the same time.

Radium and the x-ray have been very actively

exploited during the last five years especially, but unfortunately the actual death-rate from malignant tumors has not decreased materially if at all over the country, as shown by the United States Mortality Reports; while in New York City, as we shall see, where these agents are in most active use, and where, perhaps, there is more radium than in any other city, the mortality from cancer has risen more than before, and has actually exceeded that from tuberculosis, during the past six months.

It does certainly seem that it is time to carefully investigate where the error lies, and to endeavor to correct it. What experimental laboratory work, and intense and good surgical activity has failed to accomplish, careful clinical study, with patience and keen medical acumen can and should accomplish, even as they have done in tuberculosis, in spite of the continued activity of the almost omnipresent tubercle bacillus in the bodies of all of us.

During 1920, according to the records of the Health department, there were 72,525 deaths from all causes in New York City, against 74,419 in 1919, or 1894 fewer deaths, a diminution of over 2.5 per cent.

During this same year there were 5,361 deaths recorded from cancer, against 5,026 in 1919, an increase of 335, or over 6.6 per cent.; whereas the general yearly increase in cancer mortality in the whole United States has commonly been between 2 and 3 per cent.

With tuberculosis the story is quite different. In 1919 there were 7,396 deaths from tuberculosis in New York City, and in 1920 only 6,243—a decrease of 1,153, or 15.5 per cent. This seems hardly possible, but all the figures, compared with the original in the Weekly Bulletin of the Health Department have been gone over several times. Last year there was also a great drop from the preceding year in the mortality from tuberculosis, with also a very considerable rise in the number of cancer deaths during that year. There was thus, in 1919, an approach of the two of fully 20 per cent., and it was predicted that if this rate of change continued it would not take many years for cancer to outstrip tuberculosis in mortality.

But we were hardly prepared for the revelations made by the figures of the Board of Health for the last six months of this year, 1920, July 1 to December 31. During this period there were 2,691 deaths recorded from cancer, and only 2,669 from tuberculosis, giving an excess of 22 cancer deaths: That is, cancer mortality has already outstripped that of tuberculosis in this city, during the past six months! Whether this disproportion will continue, or what the future will show cannot be predicted.

The greatest number of deaths from cancer in one week was 125, in the week ending January 31, an average of almost 18 a day. The next largest was in the week ending December 4, when there were 121, or over 17 per day. There were 28 weeks which each gave over 100 deaths from cancer. It would be interesting to know where these deaths occur. Personally, I know of very few in public or private practice. It is to be remembered that while the diagnosis is pretty cer-

tain to be correct when there is a death from cancer, these figures do not, in all probability, represent the true mortality from the disease, for undertakers and others have told me that they have repeatedly known of instances where the word cancer was omitted from the death certificate, for personal or family reasons.

This is not the place to enter upon a discussion of measures other than surgery to combat the steadily increasing mortality of cancer, as this has been abundantly shown elsewhere, but only to call the serious attention of medical men of intelligence to the importance of studying cancer along the lines which already have been repeatedly laid down. And I can assure them that very much greater success will surely follow the careful and prolonged employment of proper medical measures, carefully directed to combat the basic causes of the malady, than can possibly accrue from simply excising or treating the local lesion, which is only the product of long continued systemic disorder or errors, largely from errors in living.

10 EAST SIXTY-FIRST STREET.

A SUGGESTION FOR THE COVERING OF THE YANKAUER STYLE ANESTHESIA MASK.*

By SAMUEL K. LEVY, M.D.,

BROOKLYN, NEW YORK

CLINICAL ASSISTANT IN SURGICAL O. P. D. OF BROOKLYN HOSPITAL
AND PEDIATRIC O. P. D. OF JEWISH HOSPITAL

THERE are several modifications of the original Yankauer wire-meshed mask, to all of which this method may be satisfactorily applied. I had never heard of this covering having been formerly used, and was greatly surprised on reviewing the English literature to find that no record appears of the previous use of thin layers of absorbent cotton as a covering for these masks.

I recommend covering the mask with this absorbent cotton as satisfactory and economical in administering ethyl chloride, chloroform, and ether, and I might mention that several colleagues who have given it a thorough trial speak very favorably of it. Many hospitals are now making use of pads of gauze, which are repeatedly re-washed, which from the economic point of view is quite satisfactory. However, this is not the method which meets with favor on the part of those who only occasionally have to administer an anesthetic.

Watson¹ says, "The chloroform or ether mask should have one-eighth to one-quarter-inch thickness of gauze," which necessitates the use of considerable gauze. Flagg² says, "Stockinet bandage, being more closely woven than gauze, has been found to give a more satisfactory evaporating surface." I believe that the texture of surgical absorbent cotton offers an even better evaporating surface. Considering the relative cheapness and the small amount of cotton used and the very good results obtained, I believe this to be the ideal open mask covering. Of course, the cotton used is discarded at the completion of the anesthesia.

To cover the original wire meshed Yankauer mask, I make use of the one-pound rolls of the

Grade A hospital absorbent cotton. I cut out a section about seven inches square and then use but one-half the thickness of this layer. This gives sufficient thickness to permit ready vaporization and absorption. This thickness will likely vary with different men, as does the original gauze or surgical lint covering. I now place over this cotton a single layer of gauze, merely for ease of carrying, to keep the cotton in place.

Another great advantage in this covering is that while administering, the anesthetist is much better able to observe the absorption of the anesthetic and so the need of more.

Medicolegal Notes.

Employers Liable to Free Hospital for Service Under Workmen's Compensation Act.—In an action by hospital trustees against an employer of labor for hospital service rendered the defendant's employees from time to time, liability was denied on the ground that, under its charter, the hospital is not authorized to charge for the service rendered. The hospital was incorporated by special act in 1887 as a State hospital for the purpose of providing "care and treatment of persons injured in and about mines, workshops and railroads, and all other laboring men" in the middle coal field district of Pennsylvania. For patients in this class no charge is allowable under the act. It was held, however, that the employer was liable under the Workmen's Compensation Act of 1915. At the time the special act of 1887 was passed no obligation on the part of the employer existed to furnish aid of any sort to those injured while in his service. The act of 1915 changed the status of the employer by creating a duty not previously existing and also a condition not in contemplation of the Legislature at the time of passage of the 1887 act. The 1915 act is a general law applicable throughout the State and makes no attempt to exempt from liability a class of employers within a particular district and impose upon the State the burden they would thus escape. It was also held that in view of Section 306 (e) of the act, providing that the employer shall furnish hospital services during the first fourteen days after disability, a coal company which knowingly permits its employees to be moved to a hospital without objection performs its legal duty and renders itself liable to the hospital, no formal application by the injured employees for assistance being necessary as a condition precedent to liability.—*Trustees of State Hospital of Middle Coal Field of Pennsylvania v. Lehigh Valley Coal Co., Pennsylvania Supreme Court, 110 Atl. 255.*

Construction of Statute as to Itinerant Vendors of Drugs.—A Nebraska statute, Rev. St. 1913, section 2726, provides that "any itinerant vendor of any drug, nostrum, ointment, or appliance of any kind intended for the treatment of any disease or injury, or who shall by writing, printing, or any other method, publicly profess to cure or treat disease or injury, or deformity, by any drug, nostrum, manipulation, or other expedient, shall be deemed guilty of a misdemeanor." It is held that this section does not describe two classes of offenses, one for vending and another for publicly professing to cure; and to constitute the offense an accused itinerant vendor must "publicly profess to cure or treat diseases." One reason for this interpretation was that a law attempting to limit the sale of patent and proprietary medicines to pharmacists would be a law tending to create a monopoly not necessary for public health or safety, and therefore unconstitutional and void. (People v. Wilson, 249 Ill. 195, 94 N. E. 141, 35 L. R. A. N. S. 1074.)—*J. K. Watkins Medical Co. v. Hunt (Nebr.), 177 N. W. 462.*

REPORT OF THE SURGEON-GENERAL OF THE NAVY.

IN his report for 1920 Surgeon-General Braisted concludes the story of the war work of the Medical Department of the Navy and directs attention to certain post-bellum difficulties and conditions encountered in the conduct of the affairs of this important service. Not the least of these difficulties involves the matter of personnel; for, as we are told, since demobilization began the Medical Department has been confronted with new problems, while the old ones have been magnified by the rearrangement of many aspects of life which, to superficial view, might seem remotely connected with any branch of naval administration, yet which are keenly felt in recruiting for the Medical, Dental, Hospital, and Nurse Corps. In other words, "the opportunities which present themselves at this moment in civil life to recent graduates of medical, dental, and pharmaceutical colleges and of nurses' training schools are far more enticing than anything the Medical Department has to offer." In order to offset this state of affairs very earnest efforts have been made during the past year to increase the professional attractiveness of the different corps. Members of the Medical Corps, particularly, have been given opportunities for special study, and it is proposed to prosecute this plan with vigor.

In this connection the Surgeon-General points out the fact that there is a radical difference between the general type of duty which develops efficiency in one corps and that which promotes it in another. For officers of the line, whose highest aim is competency to command a ship, a division, and a fleet, the sea is the best training school. It can readily be understood that this is true only to a limited degree with respect to the medical officer who, in order to progress in his work, even to prevent retrogression, must periodically avail himself of the benefits of the laboratory, the clinic, the operating theater, the comparative study of large and diversified groups of cases, and—not the least important—association with fellow practitioners. Long periods of sea service deprive the naval surgeon of all these advantages which are commonplaces in the lives of

those who choose terra firma as their field of action. In view of these facts the Surgeon-General urges a definite system by which, after each tour of sea duty, every medical officer "whose industry entitles him to consideration," shall be allowed a definite period of study leave in order that he may share the professional advantages enjoyed by those ashore. When the plan which the Surgeon-General advocates is elaborated and inaugurated on such a basis as to guarantee an equalization of the opportunities of naval surgeon with those of the army surgeon and the civil practitioner, the difficulties encountered, particularly since the war, in recruiting for the Medical Corps of the Navy will be materially lessened. The wide open door of professional opportunity, plus the youthful love of adventure, will doubtless prove valuable adjutants in the building up of the vigorous post-bellum naval medical service for which the Surgeon-General makes a strong appeal.

CANCER OF THE CERVIX UTERI BEFORE THE AGE OF THIRTY YEARS.

CANCER of the cervix is an affection of every age, its maximum of frequency being from thirty to fifty years, and it is really exceptional in persons under twenty. It is less rare between the ages of twenty and twenty-five and is as frequent between twenty-five and thirty as between sixty and seventy years of life. According to the long-established rule, virginity appears to preserve females from the development of carcinoma of the cervix but there are exceptions, since Leprévost (Thesis, Paris, 1913) has published two instances in virgins. It would seem that negroes enjoy a certain immunity to cancer of the cervix, although there are exceptions to the rule. Cancerous heredity seems to be frequent, but nulliparity does not appear to lessen the chances of early development of cancer of the cervix. On the other hand, repeated pregnancy results in a rather distinct predisposition for cancer of the cervix, but the influence of miscarriages is still a moot question. Previous infections—especially genital—are frequently noted in the antecedents of cancer patients, and it is perhaps possible that syphilis plays a certain part in the development of carcinoma.

The onset of carcinoma of the cervix is invariably insidious, with a long period of latency, so that it is rarely discovered in its early stages. The signal of alarm is variable. Sometimes the menses are more abundant than usual, at others there are intermenstrual hemorrhages or white, yellow or reddish discharge; pain as a symptom is rarely noted. However, roughly speaking, pain is earlier in appearance and more constant in young women than in those past the age of thirty.

The evolution of cancer is unquestionably much more rapid before the age of thirty, and this may be said to be the chief clinical character of carcinoma in young women. In a female sixty years of age it is not uncommon for the malignant process

to last for years. On the contrary, in young women cases have been recorded in which the evolution of the affection was a matter of only some months. Occasionally, in spite of this rapid evolution, the general health remains satisfactory and consequently conceals lesions that are quite advanced. On the other hand, it may be only a few months after the appearance of the first symptoms that the progress of the affection rapidly reaches the place of cachexia. But it is to be recalled that exceptionally, carcinoma of the cervix in young women may assume a slow evolution. This generally rapid evolution of the process in young women under thirty years of age places them in bad conditions from the viewpoint of a radical operation.

If the exceptional cases be put aside, in which the disease has been detected in the very early phase or even the onset, the patients are seen too late by the surgeon, and this for several reasons. Many women are neglectful or ignorant in respect to their genital life and often fear examination. The rapid evolution of the lesions is another reason, and lastly, the extreme frequency of immediate or late return of the process after operation makes the outlook bad. This does not imply that operation should be refused young subjects with carcinoma of the cervix, only that at the time of life under consideration the operative successes are not so perfect, are less frequent, and especially are less durable than in older women.

PSYCHOGENIC PSEUDOTUBERCULOSIS.

SEVERAL years ago a young woman of unusually sound health received the news that a relative had dropped dead. She bore the experience with fortitude and was soon back at her occupation. However she rapidly developed a syndrome of acute phthisis with progressive emaciation, cough, and night sweats, so that her physician on her first visit to him was almost convinced that she was tuberculous. He deferred giving his opinion until the next visit, when he found the patient quite free from symptoms, and the psychogenic nature of the latter became apparent when the patient later presented another syndrome of cardiac stasis, which passed off and left her in her usual health. During the latter experience she had gone to her daily business with ankles so swollen that she could not button her shoes. Both syndromes cleared up spontaneously.

In the November 13 number of the *Bulletin Médical* (xxxiv, 53) de Fleury has a paper on false tuberculosis of psychopathic nature and a comparison of his finds with the above mentioned case should be of interest. This author sketches his type as follows: at the tuberculous age a young man or woman begins to decline in health which, let us say, has never been robust. There is a condition of lassitude, fatigability, and anemia which disquiets the relatives. The patient seems to slip into the state of tuberculosis. But this type is not the one which really interests the author. There are young people whose health is vigorous and whose high spirits make them conspicuous, who

shock their friends by passing without warning into a state of malnutrition. In such cases the author expressly states that no psychic shock or vexation has preceded the symptoms, no physical overstrain, nothing to accuse in connection with the sudden failure of health. Relatives and friends become alarmed and summon medical counsel. Examination proves negative. The condition progresses and in some respects suggests Graves's disease, presenting symptoms common to both it and incipient tuberculosis, such as tachycardia, sweating, etc. Tremor may be marked. The patient is impressionable and becomes badly frightened over his condition. The symptoms are conflicting enough. Fever may be absent. Low blood pressure is usually found. To give the patient the benefit of the doubt he is given sanatorium treatment under which he does not prosper. He cannot be made to gain a pound and his neurotic symptoms seem out of proportion to the disturbances of general health. One might term the patient a tuberculo-neurasthenic with his peculiar mental state, insomnia, tremor, etc. A consultation held between an expert phthisiologist and neurologist will bring out the fact that the condition is purely neurotic. The cough is a nervous cough and the subject can be diverted so that it will disappear. Tachycardia, night sweats, anorexia are all psychogenic. The condition of hypochondria is the very reverse of the optimism of the tuberculous. The author especially states, however, in connection with the mental depression that it may be cyclothymic and be followed by a wave of mental exaltation. During this phase the tuberculous syndrome recedes. Under the circumstances one might wrongly conclude that the patient's optimism was the direct result of recovery. It is evident that these endogenous cases of de Fleury have hardly anything in common with the case cited by the editor in which a very short-lived imitation of beginning tuberculosis occurred in a non-neurotic subject as the result of psychic trauma.

PRE-ROSEOLOUS SYPHILITIC PERIOSTITIS.

PERIOSTITIS anticipating the roseola of syphilis is not a newly observed phenomenon and Chatellier of Toulouse gives an account of old observations as a preface to his personal experience related in the *Annales de dermatologie et de syphiligraphie*, 1920, vi, 10. In 1802 Benjamin Bell stated that the periosteum could be attacked at the moment of the generalization of the disease. Ricord was also familiar with the manifestation but attributed it to injudicious treatment. The first actual case was reported by Vidal de Cassis in 1854. A young man developed periostitis of the clavicle 25 days after the chancre. Here the author gets a trifle mixed in his dates, for he credits Schwediaur with the next case. This author should have antedated Bell, and in any case holds the record for he saw periostitis develop in the humerus five days after the chancre. It is likely that Chatellier does not recognize this observation as genuine or germane to the subject and sets it down for what it is worth.

The first real treatise on the subject was by Mauriac in 1872, in connection with his monograph on periostoses. In this he enumerates 10 cases, in all of which the appearance of periostitis could be reckoned by days following infection. In this series the periostitis antedated the roseola. Alamartine, Popescu, Nadaud (Mauriac), Rollet, and Fournier all added to the material. One readily passes from pre-roseolous periostitic to pre-roseolous meningitis and other very early accidents. This is complicated by the phenomenon of delayed roseola, formerly often seen under the early intensive mercurial treatment; so that whosoever reports a case of pre-roseolous lesions must discount the effects of the treatment. The subject, however, is not of such burning significance today, for the chancre means that the constitution is already impregnated with the disease, save for the brief initial period when autoinoculation is possible.

In Chatellier's case the subject was an infant but 18 months old. The primary lesion had appeared, several weeks before consultation, on the lumbar region. There could be no possible doubt as to the diagnosis, but the mode of inoculation was not even surmised. There had been no abortive treatment nor any specific treatment at all. Only a few days after the presence of the chancre had been noted, the infant showed troubles of locomotion. The left leg seemed to be at fault and the tibia was swollen. A periosteal focus could be palpated. A similar focus was made out on the right humerus. The diagnosis was precocious syphilitic periostitis in advance of the roseola. Intensive treatment was at once begun—hypodermics of sulpharsenol. The lesions healed completely.

HOSPITAL VS. HOME IN OBSTETRICAL PRACTICE.

At a meeting of the Royal Academy of Medicine, Ireland, held on November 12 in Dublin, Dr. Hastings Tweedy, the President, delivered his inaugural address, taking as his subject "Recent Progress in Obstetrics." He passed in review the improved treatment by the Dublin method of accidental hemorrhage and eclampsid. With regard to the treatment of contracted pelvis, he insisted that it had gained by the introduction of pubiotomy and lower segment cesarean section, as practised by Prof. Munro Kerr. He stated that in his opinion classical cesarean section would in future be reserved for emergencies when speed was an important element. It was a dangerous operation in both its immediate and after results, and was at present performed much too frequently, and often cloaked an imperfect obstetrical knowledge. It may be said, however, that some who joined in the discussion were not convinced of the adequacy of the lower segment section and were still in favor of the ordinary cesarean operation. The most interesting part of the address was that which dealt with obstetrical private practice, the practice which has been so severely animadverted against by recent writers. However, Tweedy thinks that a great change for the better has occurred in private practice, three influences having combined

to bring this about: (1) the popularity of the private hospital, or nursing home; (2) the introduction of scopolamine, and (3) the use of pituitary extract. In his experience patients now have a more uneventful convalescence in the home than in the private house, the reason for this being largely that in the latter aseptic conditions are usually impossible of attainment, nursing is frequently inadequate and unsatisfactory, the bed is unsuitable, and the light is indifferent. In the lying-in hospital all these disadvantages are done away with. It is encouraging to learn that in Dublin, at any rate, the practice of obstetrics is exhibiting improvement. While the questions of the lower segment section and the administration of pituitary extract in the first stage are debatable to a certain extent, that of the superiority of a well ordered lying-in hospital over the ordinary dwelling for the management of an obstetrical case does not seem to admit of argument. In England it is said to be the scarcity of such homes and of maternity hospitals which is responsible for many obstetrical fatalities and disabilities. In the report of the British Ministry of Health published recently much stress is laid upon the necessity for establishing institutions and homes in Great Britain for the proper treatment of obstetrical cases.

RADIUM IN EPILEPSY.

KUMMER writes briefly on this subject in the *Revue médicale de la Suisse romande* for October, 1920, xl, 10. Reports which have come in thus far are conflicting. Numerous animal experiments have been performed to determine the action of radium on the brain. Danysz, for example, placed a bit of radium under the scalp in young mice and in a few hours paralysis and ataxia supervened, followed by spasmodic contractions and death. Obersteiner found that radium could induce meningo-encephalic hyperemia and degeneration of the endothelium of the blood vessels, but the brain cells proper were uninfluenced. Further study confirmed the fact that the action of the radium is limited to the blood vessels. Tests on human epileptics showed that radium may either ameliorate or aggravate the paroxysms and the type of the disease. The indications must therefore be restricted and carefully selected. Good results have been seen in convulsions persisting after extirpation of a focus and in a case thought to be due to meningeal irritation. The author relates in great detail a case of traumatic epilepsy with trephining, evacuation of a large clot, ligation of the meningeal artery, suture of the dura, etc. The patient later became badly addicted to alcohol and had many convulsions together with an attack of delirium tremens. When he came under the author's care as a confirmed epileptic he was given radium treatment and bromides, the latter on general principles, although when given alone they had not abated the frequency of the convulsions. Radium in this case appeared able to suppress the convulsions, and whenever they reappeared its good effects were maintained. Its action on the brain outside of this was decidedly narcotizing, a fact which the author had not seen mentioned. The narcolepsy, while profound, lasted but ten minutes.

News of the Week.

Opposition by the Public Health Committee of the Academy of Medicine to the Jones Bill.—The Public Health Committee of the New York Academy of Medicine has sent the following letter to Senator Wesley L. Jones in opposition to the bill limiting the traffic in crude opium and cocoa:

U. S. Senate,
Washington, D. C.

My Dear Senator:

The Public Health Committee of the New York Academy of Medicine has given a great deal of consideration to your bill No. 4553, which prohibits the exportation from and transit through the country of habit-forming drugs and restricts imports to such amounts of crude opium and cocoa leaves as the United States Public Health Service may determine. The Public Health Committee is in full sympathy with the motive of this bill but desires to point out certain difficulties which would arise if this bill were enacted into law.

1. To entrust to official discretion the determination of the amount of crude drugs to be imported into the United States for medicinal purposes is likely to result in there being no reserve for unforeseen emergencies; first, because of the limitation of the supply, and secondly, because of the probable deflection of a certain amount into illicit channels, creating a dearth of the drugs for legitimate medical purposes and resulting in a great deal of suffering.

2. The limitation of imports, as proposed will create a tendency to smuggling with which, in view of the difficulty of trading small amounts which could be sent in letters and other ways, it would be exceedingly difficult for even a large force of Custom House officials to cope. In other words, legitimate users will be handicapped while those whom we try to protect will not be benefited by the legislation.

3. If the present law should be amended to incorporate the provisions of article 13 of the Hague Convention of 1912, that is, to limit the exportation of drugs to such persons in foreign countries as have special authorization or permits from their respective governments for the importation of the drugs in question, sufficient control would have been provided for the protection of the drug habitués in foreign countries and, moreover, this would be more in accordance with the provisions of the aforesaid treaty than the complete prohibition of exports.

4. The limitation of imports to but crude opium and cocoa leaves would mean that no morphine, codeine, cocaine, and other preparations could be obtained in this country except of local manufacture, which would be a trade protective measure of an extreme character and it will inevitably tend to increase the price of these products for legitimate purposes.

These are the principal reasons why the committee is opposed to the passage of the bill as proposed by you. In the opinion of the committee such a law will only be unduly restrictive on those who will legitimately have to use the drugs

and it will not in any way change conditions it is intended to ameliorate. We sincerely hope that you will give thoughtful consideration to the objections raised by the committee.

Very truly yours,

CHARLES L. DANA, M.D.,
Chairman.

"Sleeping Sickness" Spreads.—Reports of the prevalence of so-called sleeping sickness are coming in from very widely separated localities. The disease is on the increase in Sweden and a number of deaths from this cause have been reported in Copenhagen. Sleeping sickness has appeared in Vera Cruz in a form claimed by physicians to be the same as the African disease bearing this name. Thirteen cases of lethargic encephalitis were reported to the Chicago Health Department between January 4 and 18. A few cases are being reported in New York City.

Relief Funds Stolen.—The Vienna offices of the American Quakers' Society, which has been engaged in relief work in Austria-Hungary, were recently entered by burglars and one million crowns stolen.

French Academy of Medicine Urges War on Typhoid.—According to a special cablegram to the *New York Times*, the French Academy of Medicine, at its meeting on January 18, recommended compulsory inoculation against typhoid fever of all adolescents. A commission was appointed to study the question, and, if found desirable, to lay proposals before public authorities. During the discussion it was pointed out by Dr. Chauffard that there had been no cases of typhoid fever among demobilized men who were inoculated while in the service. Statistics were presented showing that while the proportion of typhoid cases among men of the younger age groups had diminished, that of women of the same age groups had remained stationary.

Tribute to Major-General Gorgas.—A meeting in honor of Major-General William C. Gorgas was held in the Pan-American Union Building, Washington, D. C., on the evening of January 16, at which diplomats, officers of the army and navy, members of Congress and other officials were present. The exercises were under the auspices of the Southern Society of Washington of which General Gorgas was a former president. The Ambassador of France, Major General H. K. Bethell, Military Attaché of the British Embassy, representing the British Ambassador: the Ambassador of Peru, the Ministers of Cuba and Ecuador, the Chargé d'Affaires of Panama, the Secretaries of War and Navy, Dr. L. S. Rowe, Director General of the Pan-American Union; Major General Peter Charris, Adjutant General U. S. A., and General Clarence J. Owens, Past President of the Southern Society, were the speakers. Cablegrams of tribute to General Gorgas were read from the residents of Uruguay and Costa Rica and from the Government of Colombia. Congress will be asked to make appropriation for a suitable memorial to General Gorgas to be placed in Washington, and a further tribute will be a portrait of the late Surgeon-General presented to the Government by the Southern Society, to be placed in the library of the Surgeon-General's office.

Suicides in Hungary Cause Alarm.—During the year 1920 there were 5,300 suicides in Hungary, 3,200 women and 2,100 men. In addition there were more than 10,000 unsuccessful attempts at suicide. This is causing a great deal of concern because the pre-war figures show only 50 to 60 suicides yearly. A campaign against self-destruction has been begun in which the Government, society, and church circles are cooperating.

The Medical Directory of the New York State Medical Society for 1920 has just been published. Like the earlier edition, it contains lists of licensed physicians in Connecticut and New Jersey as well as in New York State. The total number of physicians listed is 19,258, of which 14,871 are in New York State, 1,464 in Connecticut, and 2,923 in New Jersey. The total for New York City is 8,450—5,794 in Manhattan and Bronx, 2,283 in Brooklyn, 292 in Queens, and 81 in Richmond. Now that prices are falling, it is to be hoped that the next edition of the Directory will contain a little information of value to the practitioners of the State beyond the bald list of physicians. At one time, before the dues of the State Society were raised, the Directory was a really useful publication.

May Reorganize Red Cross.—Plans are under consideration for the reorganization of the thirteen physical divisions of the American Red Cross in the Continental United States. At a meeting of the central committee soon to be held a proposal will be submitted to divide the country into not more than six or seven main divisions. It is estimated that such a reorganization would result in a saving of \$500,000, without lessening the organization's efficiency or usefulness.

Judge Rules Dental Bridgework as Anatomical.—Commissioner George B. Chandler of Hartford, under the workmen's compensation law, recently rendered a decision that dental bridgework is a part of anatomy. This decision was made upon an employee's claim that his employer should pay dentistry bills or for damages to bridges sustained through physical injuries during the course of employment. Recently another commissioner decided that an artificial leg was not part of a man's anatomy, but Commissioner Chandler claims that bridgework is a more permanent part of the anatomy than an artificial leg.

A Two-Day Search for Lost Radium Needles.—Two radium needles, three-quarters of an inch long and one-sixteenth of an inch in diameter, valued at \$24,000, disappeared at the Medical Arts Building in Philadelphia on January 19, when inadvertently swept from a table in an operating room. The entire office force joined the building's porters in an all day search of the basement before the needles were found.

Law Would Ban High Heeled Shoes in Utah.—A bill has been drafted for presentation to the Utah Legislature making it a crime to possess shoes having heels more than one and a half inches in height. The bill imposes a fine of from \$25 to \$500 upon any person found with a pair of such shoes. For every additional offense the fine is from \$500 to \$1000, and imprisonment of from thirty days to one year.

Grand Jury Investigation of Drug Hospitals

Urged.—Chief Magistrate William McAdoo has submitted a request for a Grand Jury inquiry into the conditions of the municipal institutional buildings on Randalls Island and Rikers Island, where drug addicts are committed. He declares that the buildings are unsanitary and that the women's hospital is a disgrace to the city. He states that it is increasingly apparent that a separate institutional building is needed before drug addicts can be given proper care. Formerly it was possible to commit drug addicts to Bellevue, Riverside, and the Metropolitan hospitals, but owing to inadequate facilities these institutions began discharging drug addicts after ten days' treatment. They have therefore been sent to Rikers Island, which is already overcrowded, though according to Magistrate McAdoo drug addicts were given as good treatment as possible under impossible conditions.

Hospital Changes Name.—In conformity with a resolution passed by the members of the Hospital for Deformities and Joint Diseases, at a meeting held on November 14, 1920, proceedings to change the name of the hospital to "Hospital for Joint Diseases" were undertaken. Under the statute the institution had the authority to use its name from December 1, 1920.

Plans for Jewish Memorial Hospital.—The Jewish Memorial Hospital of New York, which recently purchased the large building of the Inwood Home for Girls, has commissioned architects to proceed with the plans for altering and reconstructing the present building into a complete general hospital. The estimated cost of the proposed alterations is about \$150,000.

Brooklyn Hospital Entertains Staff.—The Board of Managers of the Norwegian Lutheran Deaconesses Home and Hospital entertained the medical staff of the institution at a smoker on the evening of January 10. President Lawritz Larsen spoke for the institution and Dr. Robert E. Coughlin for the Medical Board. Addresses were also made by Dr. Lewis Stephen Pilcher of the Consulting Staff and Dr. H. Beekman Delatour of the Attending Staff.

The Bronx Hospital Organization.—At a recent meeting of the Medical Board of the Bronx Hospital and Dispensary, Dr. Wm. J. Robinson and Dr. Martin Rehling were reelected president and secretary respectively.

Dr. William H. Katzenbach has resumed his practice in New York City, and has taken offices at 139 West Seventy-eighth Street.

The Annual Benefit for the French Hospital. New York, consisting of an operative version of "Zaza" rendered in Italian, was given at the Metropolitan Opera House, on January 22, and netted the hospital \$10,000.

Charitable Gifts and Bequests.—The will of William V. S. Thorpe provides for the following bequests: Presbyterian Hospital, New York, \$50,000; Memorial Hospital, Morristown, N. J., \$25,000; the Women's and Manhattan Maternity Hospitals, each \$10,000; the Society for the Relief of Half Orphans and Destitute Children, \$5,000.

The will of Jonathan M. Parmenter of Wayland, Mass., leaves a bequest of \$200,000 for the building of a hospital in that town.

Medical Missionary Wanted for Far North.—The Board of Home Missions of the Presbyterian Church, 156 Fifth Avenue, New York, is making an appeal for an able Christian doctor to become a medical missionary at its new hospital at Point Barrow, Alaska. This is the only hospital in a thousand mile radius and the work will be similar to that of Dr. Grenfel in Labrador. The doctor's salary would be \$2,000, his house, traveling expense, and necessary equipment. A doctor with children should not apply, though it would be an advantage if the doctor's wife could become teacher of the Government school at Point Barrow, where she would receive a salary of approximately \$135 a month.

Turtle Serum Again to the Front.—According to a special cablegram to the New York *Herald*, the Berlin Medical Society has held eight meetings for the discussion of the Friedmann turtle serum. From the reports it appears that the trend of the discussion was discouraging to those who anticipated revolutionary results in the treatment of tuberculosis by the Friedmann serum. The United States Public Health Service, after quite an extended investigation, discredited the serum at the time of its trial in 1913.

Alcoholic Insanity Increases in Chicago.—According to the quarterly report of Dr. James Whitney Hall there has been an increase in the number of cases of alcoholic insanity in the Cook County Psychopathic Hospital since prohibition went into effect. The records show that in December, 1920, there was an increase of 33 per cent. in alcoholic cases over the past officially "wet" December; 16 per cent. in November; a slight increase in October and a 30 per cent. increase in September. Dr. Hall believes, however, that eventually insanity will be greatly decreased by prohibition.

Typhus Expedition Returns.—A message has been received stating that fifty-five soldiers and ten officers of the American typhus expedition to Poland has left Warsaw for Coblenz on the Rhine, the mission's time having expired. This unit has worked sixteen months with the Polish health authorities in combating typhus along the eastern frontiers. Colonel Harry L. Gilchrist, who was in command of the expedition, has had permission from the War Department to remain in Poland as adviser to the Polish Government.

The American Congress on Internal Medicine will hold its Fifth Annual Session at Baltimore, Md., February 21-26, 1921. The activities of the Congress will be largely clinical, consisting of ward walks, laboratory demonstrations, and group or amphitheater clinics by members of the medical faculties of the Johns Hopkins and Maryland universities. Further information may be secured by addressing the Secretary-General, 1002 North Dearborn Street, Chicago, Ill.

The American Society for the Control of Cancer will hold its annual meeting at its Executive Office, 25 West Forty-fifth Street, New York City, on January 29, 1921, at 4 P. M. The chief business of the meeting will be to elect officers for the coming year to receive the report of the Budget Committee, and to elect directors to fill the vacancies of those whose terms have expired.

Positions for Bacteriologists.—The United

States Civil Service Commission announces open competitive examinations to fill the positions of Bacteriologist, at \$130 to \$180 a month; Associate Bacteriologist, at \$90 to \$130 a month; Assistant Bacteriologist, at \$70 to \$90 a month, and Junior Bacteriologist, at \$70 a month. Where quarters are not furnished these salaries may be increased. For the position of bacteriologist or associate bacteriologist applicants must have graduated from a college or university of recognized standing in a course including biology and bacteriology, except that for the position of bacteriologist the completion of a three-years' course in a recognized medical college, and for the position of associate the completion of a two-years' course in a recognized medical college will be accepted in lieu of such college graduation. Applicants should apply for Form 1312, stating the title of the examination desired, to the United States Civil Service Commission, Washington, D. C., or to any of its branches. Applications will be received until July 1, 1921.

Obituary Notes.—Dr. EVA HELEN KNIGHT of New York, a physician connected with the Board of Education, died, on January 17, at the age of sixty-five years. She was a graduate of the Women's Medical College, in 1891, and was a member of the American Medical Association and the Academy of Medicine.

Dr. WILLIAM J. O'SULLIVAN, a physician and lawyer, widely known as a medicolegal expert, died after a long illness at his home in New York City, on January 20, at the age of sixty-two years. He was graduated from the Yale Medical School in 1889, and also pursued his law studies in the same institution. He was a member of the New York Bar Association and of the New York County and other medical societies.

Obituary.

GODFREY ROGER PISEK, M.D.,

NEW YORK.

Dr. GODFREY R. PISEK, Professor of Pediatrics at the New York Post-Graduate Medical School and Hospital, died suddenly of heart disease on the elevated railway station at Third Avenue and Eighteenth Street, on January 19, at the age of forty-seven years. He was a graduate of New York University, in 1894, and of the New York University Medical College in 1897. He was a member of the American Pediatric Society, the New York Academy of Medicine, the Societies of the County and State of New York, the American Medical Association, and the Post-Graduate Alumni Association, attending physician to the Post-Graduate Hospital, visiting physician to the Park Hospital, and consulting pediatricist to the Portchester, New Utrecht, and Mineola Hospitals and to the Darrach Home for Crippled Children. He was President of the Physicians' Mutual Aid Society and of the Faculty Association of the Post-Graduate Hospital. Dr. Pisek was coauthor with Dr. Henry D. Chapin of a textbook on diseases of children, and was a frequent contributor to the literature of his specialty.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, December 31, 1920.

The Patent Medicines Bill.—Reference has been made in previous letters to a proposed bill to do away with at least some of the abuses engendered by the practically unrestricted or rather unregulated sale of patent medicines in this country. More license is probably allowed to the proprietors and vendors of cure alls in Great Britain than anywhere else and this in spite of the fact that the medical profession for some time past have protested against the continuance of the abuse and by means of their official organ, the *British Medical Journal*, have investigated the matter and had made public the composition of most of these medicines and the devious ways of those interested in their sale. However, the patent medicine trade is enormously profitable, and the general public being notoriously gullible with respect to questions of medical treatment, it is difficult to educate the mass of the population and to carry conviction that the unregulated sale of patent medicines is a distinct menace to health. In any event, although the Select Committee on Patent Medicines appointed by the Government has made several recommendations calculated to curb some of the activities of the patent medicine proprietors, much delay has been experienced in attempting to introduce measures to bring into effect these recommendations. No bill will be brought in during the present session. Dr. Addison has stated that it is purposed to introduce next session a bill giving effect to the proposals which had now been agreed upon by the parties concerned. Laws with regard to the labelling and sale of patent medicines are more lax by far in this country than in America. Of course it is impossible to treat an individual in ill health properly, unless the case is accurately diagnosed. It is equally obvious that neither the sufferer nor an unqualified person is competent to achieve this result. Therefore, it really comes to this that no one but a qualified person should be allowed to prescribe. However, as this result is impossible to bring about it only remains for the Government to protect the public as far as possible by sane regulations as to the sale of patent medicines. It must always be borne in mind that there is a wide distinction between patent and proprietary medicines.

Meeting of the Society of Medical Officers of Health.—A meeting of this society was held in London on December 7, 1920, when Prof. Dr. H. R. Kenwood read a paper on the work of the Army, Navy, and R. A. F. group within the Society. In the course of his address he referred to certain diseases, influenza in particular, which needed organized research on a very comprehensive scale in order to study their behavior in the community and views with reference to epidemics generally were discussed. He was satisfied that the lack of susceptible population was not the main cause of the cessation of epidemics. He went on to point out that in the great war pre-

ventive inoculations were practised to an unprecedented degree, and death in many forms was thereby prevented to an unprecedented degree. He then asked the question, was our civil community to benefit more fully from this experience? He next discussed some respects in which co-operation should be developed between the civil public health staffs and the service sanitary staffs, and the advantages and economy that would thereby result. Professor Kenwood laid especial stress upon the necessity for devising fuller measures for the mutual protection of the civil and military population against the spread of venereal disease and pointed out that here was an enormous wastage in the fighting efficiencies which could and must be reduced in the future. It had been learned from the army how to meet many sanitary requirements by means of simple and inexpensive appliances, as fever hospitals, etc. Was the civil community going to profit from this lesson? The extravagant cost of many civil provisions had had the effect of limiting their adoption by smaller communities where they were often greatly needed. Could not a happy mean be established between the two extremes? In the discussion that followed Dr. John Robertson, Medical Officer of Health of Birmingham, drew attention to the fact that it was wise to expect nothing from the men but what they were actually expected to do. He had been appalled at the lack of cleanly habits in the men. To encourage good ventilation they must be provided with blankets and proper means of warming. It ought to be proper to prevent verminousness under all conditions and there should be a regular weekly issue of clean clothing. Dr. Robertson emphasized the importance of proper spacing of individuals in schools, hutments, etc., and said he thought that an 8-foot distance between man and man in tents would have almost prevented the spread of cerebrospinal fever. Young officers must be taught to keep to proper sanitary standards, and the reasons should be explained to them. The available information as to sanitary matters in the war ought to be recorded and collated for future use. Professor R. W. G. S. Bond, Naval Medical College, Greenwich, referred to the fact that the problem of air space, ventilation, and spacing was of the first importance on warships, and was accentuated by the crowding of extra men on board during the war. Diseases of respiration were prevalent, and influenza was very bad on ships during the outbreak. Before the war the medical officer on a ship had to act as medical officer of health even if he lacked proper training. During the war a naval sanitary service was founded. Naval health officers had since been appointed at some of the principal ports, and it was hoped that the service would be further extended.

Snow Blindness.—A paper of somewhat exceptional interest was read by Lieutenant-Commander E. L. Atkinson, R. N., at a meeting of the War Section of the Royal Society of Medicine on December 13, 1920. The subject of the paper was Snow Blindness and was based on the experiences of the author in the Antarctic, 1911-13, the winter campaign in France in 1916 to 1917, and the northern Russian front in 1919. In his opin-

ion two different sets of symptoms result. (1) Selective reflection of violet and ultraviolet rays from the sun at maximum altitude at midday. This is intensified by the conditions prevailing, excessive illumination and by the increase of the number of rays striking the eyes owing to the countless ice-crystals. Fifteen minutes of such a day will cause snow blindness, the ordinary symptoms being photophobia, lacrymation, and chemosis. Contrary to the usual belief that the symptoms come on after an interval of several hours, Atkinson holds that they develop rapidly and especially on entering a tent in which a primus stove is burning. Recovery is the rule. It is the general opinion that the ultraviolet rays bring on snow blindness, and among those who took part in the discussion Mr. A. W. Ormond was the only one who did not fall in with this view. According to his experience the results appear to be secondary to the effect on conjunctive and cornea. He thinks that snow blindness is probably commonest as the result of exposure in a haze. (2) The second class is complicated by diplopia probably due to excessive strain on the internal and external ocular muscles caused by the unusual diffusion of light, resulting in the absence of any stimulus making for the fixation of the two eyes on a single point. The most efficient remedy is hemisine 1 in 1,000, which is painless. Prevention also is by no means difficult. Good glasses, which will give sufficient contrast and cut out the violet end of the spectrum, will achieve this end. Both theory and experience indicate that red and dark amber glasses are the best, which should be provided with side pieces to shut off the lateral light. However, for those who are not going on long journeys in regions of snow and ice, but who intend to spend a few weeks in the Rockies or in Switzerland, ordinary smoked glasses will, as a rule, be found to answer the purpose sufficiently well.

The Horsley Memorial.—That a memorial was to be raised to the late Sir Victor Horsley has been referred to on more than one occasion in these letters. It has been decided that the memorial shall take the form of a lectureship or scholarship to commemorate the services of Sir Victor Horsley to science and to the empire. There is no need to recapitulate the great work that Horsley did in the realms of science. He was a pioneer in brain surgery and one of the few really great names in medical science of the past fifty years.

Conference of Educational Associations in London.—The Conference of Educational Associations has been held recently at University College, London. At the joint meeting of the Associations of Head Mistresses and Assistant Mistresses a notable paper was read by Miss S. Margery Fry on "The Community and the Criminal." Miss Fry said in part that penology, if it ever came to be regarded in this country as a definite science, as it was in America, must stand half way between medicine and education. The criminal must be regarded as somebody to be cured or taught, rather than as somebody to be repressed or turned into a horrible example for the benefit of the remainder of the community. She hoped that the Birmingham magistrates' scheme under which

prisoners who displayed abnormality were medically examined, would become general throughout the country. A mental and psychological specialist should be at once appointed at Brixton Prison, the biggest remand prison in London, so that prisoners under remand could be carefully examined and every great prison in the country should be provided with a specialist who could advise about the mental condition of prisoners. Miss Fry pointed out that it was important to stop young people who were on the brink of crime, and proper examination of young criminals in the making would do great deal in this connection.

New Medical Record for Panel Patients.—The new form of medical record for insured persons has just been issued by the Ministry of Health. The new record consists of a card on one side of which are such personal particulars as the name and address of the patient and his approved society, the other side being left for the doctor's clinical notes. To insure privacy for the medical particulars the card is inclosed in a "window" envelope with a gummed label. In ordinary circumstances the record will be in the custody of the insured person's own doctor. When it passes out of his hands because the patient moves to another district, it will be sent inclosed in the sealed "window" envelope, only such particulars being shown as are necessary for transmitting it through the insurance committee of the new doctor. In this way a permanent record will follow the insured person from one district to another and will place at the disposal of each doctor under whose care he passes, a medical history which will often be of material assistance in diagnosis and treatment. The accumulated experience of illnesses shown on the records will also afford information of great value in the advancement of medical knowledge.

Honors for Medical Editors.—In the list of New Year Honors appeared the names of Dr. S. Squire Sprigge, editor of the *Lancet*, and of Dr. Dawson Williams, editor of the *British Medical Journal*. Both of these able representatives of medical journalism have received the honor of knighthood. This is the first time in Great Britain that the services of medical editors have been thus appreciated by the Government of this country. Literary men and actors galore have received recognition, but medical journalism has been left out in the cold. However, it is a wise new departure and no men from the standpoints of ability and personality in the entire list of New Year's Honors, are more deserving of official approval. It may be added that not only have these representatives of medical journalism been honored on account of their own mental gifts and of the good work they have performed in the service of medical science and their country but medical journalism in their persons has received seemly recognition.

Obituary.—Dr. George Peacock, a well known physician of Dublin, died on Christmas morning after an illness of only a few days. Dr. Peacock was a comparatively young man, 50 years of age, and always appeared to be in good health. However, he fell a victim to pneumonia, a disease which is generally most deadly to those of robust constitution. He was educated in Trinity College,

Dublin, graduating there in medicine in 1902. He was associated throughout his whole professional career with the Adelaide Hospital. He had been a vice-president of the Royal College of Physicians of Ireland. He had also held the office of president of the Section of Medicine of the Royal Academy of Medicine in Ireland and was a prolific contributor to the medical journals. He was much respected in Dublin for his professional ability as well as for his personal qualities.

Dr. JOHN KNOTT, a physician of much learning and a fluent and interesting writer on subjects along the side lines of medicine, died recently in Dublin.

Progress of Medical Science.

3. The Necessity of Maintaining Proper Standards of Nursing Care. Elisha H. Cahoon.
4. Conditions in Palestine During the War. Izak Alcazar.

2. Scoliosis.—Herman W. Marshall crystallizes his discussion of this subject in the following conclusions: 1. Acquired scoliosis developing in normal appearing, rapidly growing young patients who have no history of past anterior poliomyelitis is due primarily to unilateral congenital differences in development of spinal muscles. The onset of scoliosis is determined commonly by a lagging behind in growth and strength of the more poorly developed members in physiologically balanced, bilaterally symmetrical sets of muscles at their period of most rapid growth in adolescence. 2. Faulty blood conditions acting on unilaterally congenitally defective spinal muscles also are contributing causes frequently in developments of acquired scoliosis. Such congenitally defective muscles weaken more rapidly under the influence of faulty blood supply than homologous muscles on the opposite side of the spine, and a defective scoliotic balance develops as a result. Acquired scoliosis of vascular origin is likely to be of brief duration often because vascular defects are quickly corrected very frequently. 3. Congenital scoliosis is due at times to very marked congenital differences between homologous members of balanced spinal muscles. Differences are of such degree that normal establishment of physiological balance between them becomes impossible immediately after birth as usually takes place by hypertrophic muscular readjustments among less widely differing sets. 4. Congenital scoliosis is due at times to uncompensated congenital structural variations of vertebrae. 5. Marked congenital scoliosis is due presumably at times to combinations of slight congenital unilateral differences in muscles with slight congenital uncompensated variations in vertebrae. 6. Marked acquired scoliosis is due presumably at times to equal combinations of several contributory factors acting together to destroy muscle balance. 7. Compensated vertebral variations are of very minor importance in development of scoliosis. 8. Occupational factors act as contributory causes in development of acquired scoliosis. 9. Other contributory causes for spinal lateral curvatures are found in muscle paralysis following anterior poliomyelitis, contractures after empyema, diseases of hip joints that produce unilateral shortening of the legs, torticollis, and the malnutrition of rachitis. 10. Stabilities of balances between opposed members of sets of spinal muscles exhibit variable ranges with low and high limits that permit normal bilaterally symmetrical posture. When low limits of normal muscle balance are passed spinal deformity makes its appearance, and when upper limits of stability are approached spinal deformity is very difficult to produce, as when congenital developments are equal on the two sides of the spine in balanced muscles of exceptionally large size and strength. 11. This complete conception of scoliosis if applied in practice will modify prescriptions of special treatments to important degrees and may lead to increased efficiency in the management of cases.

6. Active Immunization by Means of Nonvirulent and Nontoxic Living Tubercle Bacilli.—Charles D. Aaron deals briefly with immunization by means of dead bacteria, which is always imperfect, in many cases complete immunity being attained only by the subsequent administration of living bacteria, because they alone can provoke the development of all the different kinds of antibodies. The use of living disease germs, therefore, remains as the most rational method of treatment. Many attempts have been made to eliminate the dangers naturally associated with this method of treatment. As might have been expected, the greatest efforts have been made to obtain a suitable vaccine possessing preventive and curative action on tuberculosis, some of which are considered briefly. No vaccines of great practical importance were obtained, however, until among the tubercle bacilli of coldblooded animals those of the turtle became of interest. These differ in certain respects from the tubercle bacilli of other coldblooded animals, and occupy a position intermediate between the latter and human tubercle bacilli, on which account they were specially suited for use in the therapy of tuberculosis. Of the utmost importance is their ability to develop vigorously at 98.6° F., wherein they differ from the tubercle bacilli of other coldblooded animals. It is noteworthy also that when cultivated at the ordinary incubator temperature they exhibit the same cultural features as human tubercle bacilli, covering the nutrient medium with a dry granular film, while at 68° F. they form a moist, creamy culture field. The original strain of the tubercle bacillus of the turtle which is employed therapeutically at the present time was isolated in 1901 by Piorkowski from two turtles which had succumbed to tuberculosis. Piorkowski's tubercle bacillus vaccine is harmless, even in large doses, has a wide range of usefulness, and is simple in application in the treatment of tuberculous patients. Just as in vaccination against smallpox, it is assumed that complete immunization against tuberculosis is established by a single injection of Piorkowski's vaccine. The injection is made with a sterile syringe at the outer edge of the gluteus maximus muscle, after sterilization of the site with tincture of iodine.

7. A Rational Interpretation of Blood Pressure Findings.—Francis Ashley Faught emphasizes the following points in this connection: 1. The systolic pressure alone should not be depended upon unless supported by the diastolic pressure, the pulse pressure, and the pulse rate. 2. The diastolic pressure is a far better and a much more accurate indication of circulatory change than the systolic pressure. 3. The cardiac rate together with the diastolic pressure may convey more information than the latter alone. 4. The complete blood pressure record is essential to diagnosis, prognosis, and as a guide to the nature of treatment and a demonstration of the effect. 5. The pulse pressure is of great value in determining the condition of the circulation and in directing the trend of treatment. 6. The pulse pressure has often a profound significance and may of itself clearly point to the diagnosis.

2. **Leucanemia.**—Douglas Symmers reports a case of this condition, which he considers probably not an independent disease, but one of a group of rapidly progressive derangements of the blood-forming tissues due to infection. Leucanemia is characterized clinically by an extremely rapid course and by changes in the blood, bone marrow, spleen, liver, and lymph nodes that partake of the nature of both pernicious anemia and myelogenous leucemia, the causative agent acting on the hematogenic centers of the bone marrow in such fashion as to produce marked numerical increase in those primitive cells which represent the precursors of both the erythroblasts and the granular leucocytes. The primitive cells in question are myeloblasts, as shown by their morphology and by the fact that they respond to the oxydase test. Histogenetically, pernicious anemia, myelogenous leucemia, and leucanemia are closely related conditions, and represent different quantitative responses on the part of the bone marrow to regenerative stimuli acting on the myeloblast.

5. **An Experimental Study of the Latent Syphilitic as a Carrier.**—Ebersson and Engman, in this preliminary report, give the results of an investigation to determine the infectivity of (1) lymphatic glands, (2) semen, (3) blood, (4) spinal fluid, and (5) nasal washings obtained from persons known to have syphilis in a latent form. The tonsils and postmortem tests were studied in too few instances to merit a detailed report of the results. They summarize their findings as follows: In this study, *Spirochæta pallida* has been isolated in five instances from latent syphilitics—three times from inguinal glands (in two women and one man) and twice from the semen. The strains produced typical syphilitic lesions in rabbits' testicles and could be recovered and propagated for an indefinite number of generations. The incubation periods of the spirochetes isolated from the glands were, respectively, 50, 54, and 133 days, the last being doubtful owing to an early secondary infection in the experimental animal. The two strains that were isolated from the semen developed after four and seven months, respectively. *Spirochæta pallida* was isolated from patients who gave a history of syphilis dating back eleven and thirteen years in two instances, and one year in three instances. An inguinal gland and the semen proved positive for spirochetes in the two cases first mentioned, and the glands and semen in the last named. In this series of positive results a gland was found to be infectious in the case of a man whose Wassermann reaction had been negative, following treatment, and at the time of taking the specimen for the experiment gave a ++ reaction only in the cholesterol antigen. A second instance of this nature was found in the case of a specimen of semen which proved positive for *Spirochæta pallida*. As far as studies with these different strains have progressed, there is no intimation that *Spirochæta pallida* has lost in virulence for the rabbit. Detailed experiments on infectivity and other phases of experimental syphilis with these and other strains will be reported subsequently. It appears from this investigation, and that of others, that the blood and other body fluids, except semen, are not infectious in latent syphilis, or, if so, but rarely. Incubation of blood from latent syphilitics did not favor any infectious property that might have existed. Thirty-six specimens, duplicates of those in the series, were incubated at 37° C. for from three days to four months before being injected into rabbits' testicles. The results were negative. One-third of the total number of spinal fluids from latent syphilitics evidenced lymphocytosis, and one gave a positive Wassermann reaction. Tonsils could

not be studied, owing to severe secondary infections that were set up in the experimental animals. In one case, a dark-field examination showed what appeared to be *Spirochæta pallida* in an emulsion of a tonsil taken from a child with a family history of syphilis, who gave a positive Wassermann reaction, although free from symptoms or visible lesions. The rabbits failed to survive injection of material. The groups of patients studied were composed of those that were untreated as well as those that had received no treatment within the last two years. Between the time of taking specimens for inoculations of rabbits and the first symptoms of a suggestive history of syphilis in these patients from one to forty years had elapsed. Out of a total of 500 cases of syphilis which were seen at the clinic, seventy-five, or exactly 15 per cent., were definitely latent. These investigations demonstrate the fact that those persons that give a history of an old syphilitic infection may harbor active virulent *Spirochæta pallida* for years, and this in the face of irregular negative Wassermann reactions or slight reactions only in the cholesterol antigen.

6. **Diagnosis of Gonorrhea in the Female by Staining Methods.**—Norris and Mickelberg give an analysis of 794 examinations from cases presenting clinical evidences of gonorrhea, drawing the following conclusions from their study: 1. When dealing with inflammatory lesions of the lower genital tract, it is advantageous to determine the type of infection present. 2. During the acute stage of the gonococcal infection the diagnosis is generally made without difficulty, as the clinical signs are more or less significant; if doubt exists, film preparations can be depended on. 3. Because of the certainty with which a positive diagnosis by staining methods can be made in the acute stage, and the many difficulties encountered in the chronic stage, it is especially important that the variety of infection present be ascertained during the acute stage. Unfortunately, many cases are not seen during the early stages, and a positive diagnosis is therefore arrived at only with difficulty. 4. During the chronic stage the clinical signs are less characteristic than during the acute stage. 5. The examination of film preparations is less satisfactory. 6. The presence of gonococci can be demonstrated by film preparations from every case if a sufficient number of correctly performed examinations are made. 7. A single negative smear examination is without significance. In such a case the chances of demonstrating gonococci are about three or five to one, according to the skill of the examiner. 8. Even under the most favorable circumstances, positive film examinations can be obtained in only a relatively small proportion of cases. 9. Unless safeguarded by the Gram stain or one of its modifications, smear examinations are valueless. 10. Even with Gram's stain, errors in diagnosis may occur. Differences in the thickness of the preparations, slight overstaining or understaining, etc., may lead to extremely misleading results. 11. Owing to the many difficulties surrounding this form of diagnosis, they believe that unless the test is performed by one experienced in the work its results are of no value, and are often actually misleading. 12. Clinical evidence is of far greater value than staining methods, even when the latter are performed by an expert. 13. From a practical standpoint, all cases should be regarded as of gonococcal origin until proved otherwise. 14. Without desiring to underrate the value of staining methods in diagnosis, it is nevertheless believed that their usefulness has been considerably overestimated.

3. The Treatment of Large Defects in Peripheral Nerve Injuries.—John S. B. Stopford, in the course of his investigations for the Medical Research Council, had the opportunity of estimating the advantages and disadvantages of many of the operations which have been advocated at various times to cope with this problem of a "gap." He summarizes these observations as follows: 1. No clinical evidence of regeneration has been found after the flap operation (three patients), incomplete nerve crossing (seven patients), or bridging (thirty patients). 2. Definite and satisfactory regeneration has occurred after transplantation of the ulnar in front of the internal condyle of the humerus in all the twenty-nine patients examined. It seems probable that both the motor and sensory recovery will be more complete after this maneuver than in the series of simple end-to-end suture without displacement. 3. Normal recovery, as after end-to-end suture, has been seen in five out of six cases in which the two-stage operation was practised. 4. Defects may be treated with a reasonable prospect of success by the two-stage operation, or anterior displacement in the case of the ulnar, and consequently such futile procedures as the flap operation, lateral implantation, or bridging need not be considered.

5. A Note on Blood Pressure During Intravenous Injection of Quinine.—U. N. Brahmachari records seven observations made in order to determine the changes in blood pressure during intravenous injection of quinine. The injections were given in the apyrexial period, except in one case. He found that intravenous injection of quinine in concentrated solution (10 gr. in 20 c.c.) is generally followed by a fall in blood pressure and may be followed by a disappearance of the pulse for a few seconds. Intravenous injection of quinine in dilute solution (10 gr. in 200 c.c.) may be followed by a fall in blood pressure, but this fall is neither so sudden nor so great as in the case of concentrated solutions. In many cases there is no fall of blood pressure. The more slowly the injection is given the less is the chance of fall of blood pressure taking place. The diminished blood pressure may persist for twelve hours or more after the injection. Intravenous injection of quinine should always be given in very dilute form (1 in 300), and at the rate of 10 c.c. every minute. It should never be lightly undertaken. In concentrated solution intravenous injection of quinine may be followed by transient muscular twitchings and quickness of breathing. The injection should be given after making frequent and careful blood pressure observations during the operation. As in malarial fever, especially of the pernicious type, blood pressure is sometimes very low, intravenous injection of quinine should be given very slowly in a dilute form, guarded by administration of pituitrin or adrenalin and application of tight bandages over the extremities. If these precautions are taken the dangers of intravenous injection of quinine will be reduced to a minimum.

1. An Address on Stasis and the Prevention of Cancer.—A. C. Jordan points to the dangers of neglected stasis and its far-reaching consequences, and draws attention to the various ways in which cancer is brought about by stasis. In conclusion he outlines the means that should be taken to prevent the occurrence of cancer: 1. Avoid stasis in general, with its attendant toxemia; in other words, keep all the tissues healthy. 2. Avoid sources of local irritation in the alimentary tract: (a) In the lips and mouth and tongue—avoid rough pipe stems, jagged teeth; abolish pyorrhea. (b) In the pharynx and larynx—eliminate chronic catarrh. (c) In the esophagus—swallow no large boluses of food; eat slowly; masticate thoroughly. (d) In the esophagus and stomach—avoid excess of strong irritant spices (for

example, mustard, pepper), and avoid extremes of heat and cold, especially drinks. (e) In the stomach and duodenum—prevent duodenal distention, pyloric spasm, and duodenal and pyloric congestion by abolishing the ileal stasis which causes them. (f) In the small intestine—prevent bacterial decomposition of the contents of the jejunum and ileum due to ileal stasis. (g) In the large intestine—prevent stagnation and decomposition of solid feces in any part; combat catarrh by local and general means. The writer holds that it is never too early in life to commence these measures. In infancy, even on the first day of life, see to proper feeding. If artificial feeding is necessary the milk should be given at regular intervals in measured amounts at the correct temperature; avoid overfilling the infant's stomach. Constipation in the infant is best combated by small doses of liquid paraffin. In childhood, provision should be made for warm clothing, good regular meals, with vitamins in the diet, an active day with a midday rest, and a long, restful night. During school and college years the same conditions should be continued, with a regulated open-air life, avoiding extremes of exhausting effort, and insisting on an early hour for retiring and a minimum of eight hours in bed. In patients who have not had the advantage of suitable conditions from infancy, the exact method to adopt must depend on the precise anatomical and pathological conditions which exist. If mechanical faults are present—for example, obstruction due to bands, or to cicatrices—these must be dealt with by surgical means. If the large intestine is already grievously damaged so that it is no longer capable of repair, nothing short of its removal will avail. In less extreme cases much good may be done by careful attention to the details of hygienic living. In addition, mechanical means should be taken for supporting unduly dependent portions of the bowel, and liquid paraffin given to ensure two or three soft evacuations daily, vaccines to overcome the toxemia due to bacterial action in the large and small intestines, while medicines are useful to aid digestion, combat catarrh, and lessen spasm at the sphincters. Much can be done to prevent cancer of the pelvic organs by means which prevent or relieve chronic intestinal stasis.

3. Inflammatory Lesions of the Nasal Accessory Sinuses.—Herbert Tilley considers this subject from the point of view of the general physician and surgeon. In dealing with a patient suffering from chronic inflammation of a nasal accessory sinus the practitioner is, as a rule, only too ready to fall into the error of accepting without question or thought the sufferer's own diagnosis of "chronic nasal catarrh," which both tacitly agree to be a more or less incurable inconvenience. This "diagnosis," in the writer's opinion, is responsible for the overlooking of by far the larger proportion of cases of chronic suppuration in the nasal accessory sinuses. As a result it only too frequently happens that the patient drifts on with his so-called "catarrh," the frequently associated headache becomes an additional burden, and the general health suffers in a multitude of ways; on the other hand, to his laundry and to the purveyor of "catarrh cures" he is a perpetual source of income. When the presence of an empyema has been established no time should be wasted with nasal washes, visits to the seaside, or the use of vaccines. There is only one cure for a suppurating cavity in bone, namely, to open it freely, remove the diseased pyogenic membrane, and establish free, permanent, and spontaneous drainage until the mucous membrane has returned to its normal condition. In all cases where an inflamed accessory nasal sinus is under suspicion, especially from the point of view of systemic symptoms, its contents should be submitted to a skilled bacteriologist, who would inform one of the nature and virulence of the secretion.

5. Cervicitis, Ovarian Cyst.—Robert T. Morris, in this clinical discussion, emphasizes a point in technique

which makes for a good, strong abdominal wall at the site of the diastasis. By the sense of touch the rectus muscle is recognized on one side of the incision far away from the median line. Crowding it toward the midline with one hand allows one to incise its sheath and to expose the muscle tissue the entire length of the abdominal incision. The process is repeated on the other side. The separate planes are then all in sight, so that they may be nicely sutured in their respective positions. This he considers a pretty step in technique and one easily accomplished if one will only reach in and find the rectus muscle on each side and then crowd it up to the midline in such way that he may divide the sheath for nice anatomic repair.

Intravenous Injections of Silicate of Soda.—Scheffler, Sartory, and Pellissier first discuss the occurrence of silica in the body. In a man of average bulk there should be over 6 grams more than the iron content. The ox contains less silica than the bull, hence there is believed to be some connection between silica content and virility, specially as the content in the cow approximates that of the ox. Aside from this aspect there is diminished silica in tuberculosis and arteriosclerosis. There is a so-called "silicious anemia," a term equivalent to a general deficit in the mineral. Absence means a reduced elimination of CO₂, and in consequence an abnormal production of toxin. Silica introduced within the body of a silica-deficient subject acts as an invigorator, and thus far has been given per os, the authors having been the first to substitute the intravenous method. Given in certain doses a retention is shown by examination of the urine. Doses of several grams per os over long periods have caused no toxic symptoms. The retention is only temporary, unless presumably there was an original shortage in the total body content. The authors in this paper are concerned chiefly with the practicability of intravenous exhibition. The dose tentatively reached was 0.01 to 0.015 milligram daily, at which limit there were no accidents, the amount being a sufficient dose. The only class of affections mentioned comprise general and cerebral arteriosclerosis, angina pectoris, and syphilis of the arteries, in which conditions the injections gave prompt relief.

La Presse Médicale.

November 17, 1920, xxviii, 84.

The Reducing Power of the Tissues.—Roger shows that albuminous substances in the tissues have reducing properties. He has experimented with brain substance, liver, kidney, muscle, etc. Pulp is made and diluted with water and tubes containing the emulsion are tested under different conditions with methylene blue and other test substances. With the loss of some of its oxygen the color of the reagent disappears. It is known that all living cells, animal and vegetable, are reducing agents. This could hardly be otherwise, for they require oxygen for their metabolism and appropriate it wherever found. But to assert this property and to demonstrate it and discover its laws are different subjects. The author's studies show that liver has the greatest reducing power of any of the tissues tested. Having demonstrated the reducing properties the author sought factors which may accelerate or retard reduction. Hydrocyanic acid was found to paralyze the function although this was not completely suppressed. Roger believes that these researches may pave the way for fresh discoveries. He begins his article with a quotation from Genesis concerning the breathing of air into the senseless clay at the creation of Adam, and remarks that the prescience of the ancients seems infallible.

La Presse Médicale.

November 27, 1920, xxviii, 87.

Incumbents of the Chair of Obstetrics at the University of Paris.—In Brindeau's opening lecture before the class in obstetrics he incidentally enumerates his

predecessors in the chair. At the close of the midwife period Puzos was demonstrator of obstetrics to the class of women and hence *ex officio* becomes a sort of predecessor to the accoucheurs. In 1794, after the close of the Revolution, the chair of theory of obstetrics was created, with Leroy as titular professor. Leroy's assistant, Baudeloque, later became famous. At the time this chair existed on paper only, and there was no clinical instruction until 1829, when a clinical chair was created. Deneux, the incumbent, held on until 1830, but there was not much doing and Paul Dubois was the first real pioneer in this field, ranking among the greatest French masters, greater even than his successor, Depaul, who held the chair until 1881. It was during the latter's administration that a special maternity hospital was erected. Depaul was succeeded by Pajot, and he in turn by Tarnier. The Maternity became known as the Tarnier clinic. An overflow clinic was eventually established at the Beaujon Hospital, and this was placed in charge of Ribemont-Dessaignes, who held it until 1919, when he was succeeded by the author. Tarnier is, of course, the great historical figure in French obstetrics, and at least seven of his pupils have continued his labors at the original Maternity clinic, including Budin, Pinard, Champetier de Ribes, Auvard, Bar and Bonnaire, in addition to Ribemont-Dessaignes already mentioned.

November, 1920, xxviii, 45.

A Form of Tick Fever.—Puntoni describes a form of epidemic acarissis due to the *Pediculoides ventricosus*, which from its being accompanied in part by fever and distributed through the handling of grain has been popularly known as "grain fever" and "grain itch." This affection seems to have been first described in 1850 in France on the occasion of an epidemic which was succeeded by others in 1866 and 1872. The acarissis in the case was first studied satisfactorily by Ducey in 1908, in connection with an epidemic in Italy. The author has studied an epidemic of the same character during the past fall. He finds it of the general type of a scabies of purely local and external character. The term of "tick fever" would, of course, be misleading, for in that type of infection the tick merely transmits a parasite of which it acts as host. The presence in grain of the acarissis in question is due to the fact that it is itself a parasite of certain insects which infest the grain. There seems to be requisite an incomplete desiccation of the latter with germination. The ova of certain insects which have been deposited in the grain are favored in regard to hatching. None of the insects in question are specified. The acarissis may be regarded as an occasional parasite of man which differs from the scabies acarissis in being unable to thrive well in the human integument. Prophylaxis is difficult, but treatment is simple—in fact, the rash soon subsides of itself. Transmission from man to man is not proven. A second article on the same subject by Pantaleoni comprises an account of a personal experience. The affection diffused very rapidly in a community and some of the child victims were interned in hospitals for measles or scarlatina. Fever in some of these children reached 40° C. The hands and forearms were the first to be attacked. Another name of the parasite is *Acarus tritici*.

Poisonous Beans.—Rosenfeld refers to the bean known as the *Phaseolus lunatus* which contains an active substance known as phaseolunatin. Through the action of enzymes the latter can split off hydrocyanic acid in association with acetone and glucose. In handling, the beans should be soaked for two days in water which should be frequently changed; then boiled for 3 hours and the water thrown away. The last fresh boiling water should contain a little vinegar. [The *Phaseolus lunatus* is none other than our well-known lima bean and under the same genus we find the common pole bean. Gray states that both species were imported into the United States for cultivation as a food supply. Nothing is said of any toxic properties.]—*Wiener klinische Wochenschrift*.

Book Reviews.

SHORT TALKS ON PERSONAL AND COMMUNITY HEALTH.

By LOUIS LEHRFELD, A.M. M.D., Agent for the Prevention of Disease, Department of Public Health, Philadelphia, with an Introduction by WILMER KRUSEN, M.D., LL.D., Director (1916-1919) Department of Public Health and Charities, Philadelphia. Philadelphia: F. A. Davis Company, 1920.

The number of individual subjects discussed is over 100, grouped under seven sections which deal respectively with prevention of preventable disease, health activities of spring and summer, hygiene of holidays, food and water, infants and children, first aid and miscellaneous. In the last named the most varied topics are briefly discussed as occupation and disease, cancer, sleep, noise, barber shops, coal gas, vacant lots, foot strain, common drinking cups, swimming pools and so on through many other present day topics. The brevity and alternation of subjects obviate the possibility of dryness and theorizing, so that whoever begins the book will be likely to maintain his interest until he completes it. He can also begin at any page and read in either direction without losing anything.

ELECTRIC IONIZATION. A PRACTICAL INTRODUCTION TO ITS USE IN MEDICINE AND SURGERY. By A. R. FRIEL, M.A., M.D. (Dub.), F.R.C.S.I., Aural Specialist, Ministry of Pensions, London District, Late Physician for the Throat, Nose and Ear, General Hospital, Johannesburg. New York: William Wood and Company, 1920.

The author in this booklet of 78 pages gives credit to Professor Leduc as the originator of ionic therapy. The four chapters are devoted to the electric current in its relation to ionization, the equipment, the effects of different ions and the details of treatment. There are 25 illustrations. The chapter on treatment occupies nearly half the book. Aside from numerous references to Leduc the volume is a personal one although under certain diseases—as gynecological—other authorities are quoted as if the author had been without personal experience. Thus in gynecology he quotes Sloan and Cleaves and in pyorrhea Sturridge. He also makes citations from the textbook of Lewis Jones. The author is a recognized otologist and bacteriologist, neither of which branches leads logically to ionic surgery so that the production of a one-man book on electric ionization strikes us as an unusual but none the less creditable performance.

HANDBOOK OF DISEASES OF THE NOSE, THROAT, AND EAR. For Students and Practitioners. By W. S. SYME, M.D., F.R.F.P. and S.G., F.R.S.E., Surgeon to the Ear, Nose and Throat Hospital, Glasgow. New York: William Wood and Company, 1920.

This volume of pocket size contains 329 pages with 26 illustrations. There are nine sections, as follows: the nose, nasal accessory sinuses, nasopharynx, pharynx, larynx, syphilis in the preceding localities, direct examination, the ear, and x-ray examination. For some unknown reason there is no reference to malignant disease, despite the great advances of recent years in our knowledge of these subjects. We hope the author will rectify this omission in his second edition. In all other respects we have nothing but praise for the book.

THE MEDICAL CLINICS OF NORTH AMERICA. Published Bi-Monthly by W. B. Saunders Company, Philadelphia and London. VOLUME III. NUMBER 6. May 1920. Chicago Number. VOLUME IV. NUMBER 1. July 1920. New York Number. VOLUME IV. NUMBER 2. September 1920, Boston Number.

The Chicago number contains twenty-three presentations from the clinics of eighteen physicians in that city. Dr. Dyson does valuable service in emphasizing the desirability of determining the actual count of cells in the urine in cases of pyelitis. Williamson again demonstrates the fact that pernicious anemia can never be considered cured for recurrences have been reported after very long periods of time. Strouse discusses five cases of angioneurotic edema and urticaria and points out the danger from the presence of abdominal symptoms which may simulate acute surgical conditions.

In the New York number nineteen medical teachers present interesting and instructive cases. Foster's discussion of nephritis is compact and yet quite complete. He has touched most of the features of that disease which bother not only the student but also many practitioners. Mosenthal discusses the estimation of renal function and Cecil the prevention and serum treatment of lobar pneumonia, both in very interesting talks. Kahn has an article upon the clinical significance of acidosis in which he presents the chemistry of the subject and points out the several types of the condition. He is opposed to the administration of alkalis in the acidosis of diabetes but his argument against them does not seem to us to be very firmly founded.

In the Boston number nineteen clinics are again represented. Paul D. White and W. D. Reid point out the difficulties in making the diagnosis of mitral stenosis and the means by which they may best be overcome. H. A. Nissen presents an analytic study of 117 cases of cirrhosis of the liver showing jaundice and ascites. J. I. Grover contributes a careful study of enuresis.

The above-mentioned articles seem to stand out as deserving especial notice but they are representative of the sort of studies that one may expect to find in this publication. All of the contributions are of interest and many contain valuable matter which can be appreciated only after a careful reading. This journal is now in its fourth volume and is fulfilling amply the promises which were made in its behalf at its inception.

REFRACTION AND MOTILITY OF THE EYE WITH CHAPTERS ON COLOR BLINDNESS AND THE FIELD OF VISION. By ELLIS M. ALGER, M.D., F.A.C.S., Professor of Ophthalmology, New York Post-Graduate School. Second Revised Edition. Philadelphia: F. A. Davis Company, 1920.

This volume is a *bona fide* second edition which appears ten years after the first, several new printings in the interim counting only as the first edition. The number of pages is slightly increased and this is true of the illustrations. The chapters are the same, save the addition of an eighteenth on ocular malingering, which comprises 12 pages and is of much interest. In his preface to the second edition the author deplores the fact that Refraction is believed by many general practitioners to be almost an exact science. The absurdity of such an idea is best shown by the disparity in opinion often seen among experts.

MANUEL D'URETHROSCOPIE. Par ROBERT HENRY et ANDRÉ DEMONCHY. Préface du DR. MARION. Paris: Masson et Cie., 1920.

This work comprises 116 pages with 56 text figures and 30 colored plates. It suggests a continuation of the atlas of cystoscopy published in 1914 by Marion, Heitz-Boyer and Germain, but the authors quote extensively from the writings of Luys on gonorrhea and of Goldschmidt on irritations of Luys on gonorrhea and of Goldschmidt on irritations of Luys on gonorrhea, while the apparatus of Buerger and McCarthy of New York are fully dealt with. Demonchy, one of the authors gives much space to his own apparatus and technique and concludes that with the latter and the instrument of McCarthy all requirements of cystourethroscopy can be fulfilled. Although the book is pre-eminently diagnostic in scope there is a short section on treatment as carried out by means of the urethroscope.

DIE THERAPIE DER HAUT- UND VENERISCHEN KRANKHEITEN mit besonderer Berücksichtigung der Behandlungstechnik für Aerzte und Studierende. Von Prof. Dr. J. SCHAFFER. Fourth Edition. Berlin and Vienna: Urban & Schwarzenberg, 1919.

The first edition of this work appeared in 1915 and the rapid succession of new editions has been utilized to incorporate current progress. The work comprises two parts devoted respectively to cutaneous and venereal diseases. The number of pages is nearly 500, of which 112 are devoted to the general principles of treatment of skin diseases and about 200 to the treatment of individual dermatoses. Some 60 pages are given to the management of gonorrhea and 80 to the treatment of syphilis. There are 87 illustrations. The volume is eminently practical and rich in prescriptions and technical details. To such a degree are these in evidence that the work is almost a formulary of treatment.

Society Reports.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 25, 1920.

THE PRESIDENT, CHARLES K. CHETWOOD, IN THE CHAIR.

Symposium on Blood Transfusion.

General Introduction of the Subject.—Dr. R. OTTENBERG made this presentation in which he said that blood transfusion had been introduced shortly after the discovery of the circulation of the blood by Harvey. It was taken up with enthusiasm at that time, but as sudden deaths occurred again and again it was abandoned. From that time until the present blood transfusion had been practised from time to time and after a short enthusiasm fell into disfavor because of the many accidents that followed its use. We had now discovered the reasons for these accidents and were able to avoid them in practically every case. Dr. Ottenberg said the object of his talk was to popularize blood transfusion, which was regarded by many physicians as a desperate measure. It should not be so regarded. The first contact of the average practitioner with blood transfusion was when it was suggested by a consultant and the practitioner then called in a so-called transfusion specialist. Under such circumstances the patient was often in extremis. In other words, the general practitioner did not recognize the utility of early transfusion before the patient became desperately sick. The first question the doctor asked when brought into contact with transfusion was "Is it dangerous?" It used to be, as was shown by the many accidents that formerly occurred. It had now been made relatively safe by the tests carried out in the selection of the donor. The definite source of danger was incompatibility between the blood of the patient and that of the donor. The work of Landsteiner in 1901 and of others showed that all human beings belonged to one of four groups, that the blood of all individuals belonging to the same group was compatible, while the blood of two individuals belonging to different groups was incompatible. The incompatibility consisted in agglutination or hemolysis, or both, of the cells of one individual by the serum of the other. Of these the danger of hemolysis was greater than that of agglutination. The making of the tests required considerable care, skill, and knowledge. The Wassermann test should also be made in every case. The agglutination and hemolysis tests had been so simplified that the expert could tell in ten minutes to which group a specimen of blood belonged. Laboratories also kept a list of donors with whom they could get in touch on short notice. A specimen of blood was obtained from the patient by puncturing the finger and withdrawing five drops of blood into fifteen drops of three per cent. sodium citrate solution. This was then sent to the laboratory and the proper donor could be chosen within one-half hour. A second question which arose was whether accidents could happen even when tests were made. Dr. Ottenberg said he knew personally of three such accidents. One was due to a misunderstanding about the donor's group; two were unexplained; one of these occurred in a post partum sepsis and the other was an embolism in a case of phlebitis. Lindemann reported three accidents, two of which were due to mistakes in tests. A third question was what to do in a case which was so urgent that there was no time in which to perform the tests. Under such circumstances one was justified in going ahead and doing the transfusion, as the risk was small. Crile, in 100 cases, reported two deaths due to hemolysis, and Bernheim collected 800 cases in which hemolysis occurred 16 times with four deaths. Karsner calculated that there was no danger in over 60 per cent. of the cases. In 1909 Dr. Ottenberg had explained the safety factors and Moss had shown that there were antihemolytic substances in the blood which offered protection against hemolysis. Though hemolysis might not be fatal it interfered with the good results of transfusion. There was danger of the patient's getting a chill following transfusion in prob-

ably about 20 per cent. of the cases, and this was accompanied by a rise in temperature. This was a danger in greatly exhausted or exsanguinated patients. Another danger was that of blocking the kidneys. One case of suppression of urine following blood transfusion had come under his observation and a case was reported in the literature in which the patient died. The speaker called attention to the views expressed by Dr. Libman and himself in reference to the citrate method, stating that there seemed to be no contraindication to the use of the citrate method in hemorrhagic cases, the only condition in which some objections might be raised to its use was in hemophilia, and they believed that caution should be used in employing the citrate method in cases of renal disease. A fourth question was who would be the donor. Should the donor be a member of the family or a paid donor? In all cases in which it was possible one should take a member of the patient's family, but care should be taken not to select a nervous donor because his blood pressure might fall at the critical moment and transfusion become impossible. A donor should be selected who had a vein into which one could introduce a large needle. It was not necessary to make any scar and the donor could return to work the following day. There was no danger to the donor. As to how often a person could act as donor, he knew of several men who had acted as donors ten times, and others fifteen or twenty times. A person should not act as donor oftener than once in three months and perhaps six months. The hemoglobin should be estimated and the Wassermann test made each time before the transfusion was done, as there was a possibility that the donor might have contracted syphilis since the last transfusion. As to the amount of blood which could be taken, it was from one pint to one quart. Five hundred cubic centimeters would not harm a donor. Of that he could be assured. They had learned that it was not necessary to have extremely large amounts of blood, as frequently a lesser amount would have very beneficial results. Another question asked was whether the procedure was going to be painful. One should cocaineize the skin, but should never use adrenalin, as that would contract the veins. It was rarely necessary to cut down on the vein, though perhaps that was done oftener than it should be. With the introduction of the citrate method almost any doctor should be able to do a blood transfusion. It was more difficult to perform transfusion in infants from one to three years of age. The question of how much blood should be transfused depended upon how much the patient needed and how much the donor could spare. In acute hemorrhage the patient needed a great deal, but generally it was not necessary to give him as much as he had lost. In the chronic anemias one had to be guided more accurately. It was desirable to raise the hemoglobin as much as possible. Dr. Ottenberg gave a mathematical formula by which one could calculate the rise in hemoglobin that could be expected and showed that it was not so great as often supposed. In a typical instance cited in which the hemoglobin of the patient was 50 per cent. and that of the donor 100 per cent., the rise in hemoglobin had been only 8 per cent. However, as the result of a 1000 c.c. transfusion in the course of the subsequent days the percentage of hemoglobin was likely to go somewhat higher. The Mayos had experimented with the preparation of the patient for transfusion by having both patient and donor fast. In chronic anemias it seemed wise to have the patient somewhat dried out before transfusion; this was accomplished by giving the Karrel diet or strictly limiting the intake of fluids for a few days. Dr. Ottenberg described the advantage of the citrate method, namely, its simplicity. The Lindemann and Unger methods possessed the advantage that their use was less likely to be followed by chills. As to whether the patient needed after-care, someone must stay with him in case of chill. He should be kept warm and stimulants and hot water bags should be in readiness.

Indications for Blood Transfusion.—Dr. R. E. STERSON discussed this phase of the subject. He stated that a few years ago the enumeration of those conditions in which blood transfusion was indicated would have been an exceedingly easy task. But

in less than a decade this measure had developed from a complicated surgical operation, employed only in extremis, and then rarely, to an every-day procedure, the efficacy of which had been proven in many and varying conditions. In traumatic and post-operative hemorrhage blood transfusion had proven invaluable. In hemorrhage due to pathological conditions, as gastric ulcer, varicosities accompanying cirrhosis of the liver, typhoid ulceration, etc., transfusion was strongly indicated. There was no danger of increasing blood pressure in such conditions if proper judgment were used. Fatalities in obstetrical cases and in hemorrhage of the new born were frequently prevented by blood transfusion. It was also indicated in diseases of the blood, bone marrow, and lymphoid tissue, among which might be mentioned pernicious anemia, aplastic anemia, Von Jaksch's anemia, leucemia, chlorosis, secondary anemia, hemophilia, and purpura. Leucemia was unaffected by blood transfusion except as a very limited temporary measure of prolonging life. In hemophilia it was a temporary specific. Some cases remained normal for several years following transfusion, while others required treatment every few months. Transfusion had proven of value in a limited way in tuberculosis, syphilis, leprosy, influenza, and typhoid fever. There were, of course, only certain instances of these conditions in which transfusion was indicated. Lindemann's work in tuberculosis had never been published, but his results in some cases were truly remarkable. Transfusion was indicated in any severe purpura, but the writer's experience with those of unknown etiology, whether in childhood or old age, had not been encouraging. The most brilliant success of blood transfusion had been in combating sepsis. In no other condition had their results been so uniformly successful. Citrated blood did not act so favorably in the severe anemias as the undiluted whole blood with which they had worked. They had treated successfully cases in which sepsis was secondary to some initial focus such as otitis media, usually complicated with mastoiditis and jugular thrombosis. He could cite seven such cases with positive blood cultures of *Streptococcus hemolyticus* with seven recoveries. In cases showing the *Streptococcus viridans* and the *Streptococcus albus* in the blood cultures their results had been equally good, and also in cases which came clinically in this category in which the cultures were not taken or were sterile. Lastly the writer mentioned a group of miscellaneous conditions in which blood transfusion might be valuable, among which were malnutrition of infancy and childhood, gas poisoning, delayed coagulation time of the blood in jaundice, tropical sprue, and certain cases of infection with animal parasites in which the anemia might be extreme, as *Bothriocephalus latus* infection. Two severe cases of acne and psoriasis had been observed to clear up during transfusion.

Dr. ROBERT EMERY BRENNAN spoke of the technique of blood transfusion. He said that Carrell's technique was so difficult to acquire that its universal employment was quite impossible. The profession, however, could not very well neglect such a life-saving operation and looked for ways which would be easier of execution and prove successful at the same time. The inventions of Crile, Brewer, and Elsberg assisted materially in the simplification of the technique. Still the operation remained in the hands of a few surgeons, those who acquired the necessary dexterity by much study. By taking it out of the hands of a few expert technicians and putting it into the hands of anyone in the profession who was well grounded in the fundamentals of surgery, Dr. Lindemann had done a service for the profession for which they owed him a debt of gratitude. There were a great many ingeniously devised apparatuses on the market, well constructed, and working with precision, but why overburden our present superfluous armamentarium with a special apparatus when, as he had mentioned before, anyone with an idea of surgical technique could obtain the same results any time or any place with no special apparatus, but with the use of two 20 c.c. syringes of the Record type and two needles or special cannulae, if one preferred. Simplicity, as we knew, was the keynote of success in anything that was undertaken, and for that reason the complicated and difficult methods of blood transfusion were not universally employed by the profession. It occurred, there-

fore, to the writer to employ the following procedure, which he had been doing for years without a failure. He used two 20 c.c. Record syringes and two needles or cannulae of the same gauge (No. 13 or 14 in adults; in children one would have to resort to a smaller gauge, about No. 18 or 19). Blunting the sharp end of a long hypodermic needle would do in an emergency, the writer having had to use this procedure on many occasions. In addition, one required one-half of one per cent. novocaine, a scalpel, a pair of thumb forceps without teeth, a small rubber tourniquet, sterile mineral oil, and cold saline solution. The above-mentioned articles were sterilized by boiling, after which the syringes and cannulae were lubricated with the sterile oil. The donor and recipient were placed side by side in the prone position on tables and the arms to be used in the operation made to rest extended on some sort of platform between them, and the customary routine sterilization was carried out. An injection of the novocaine solution was made over the most visible vein, and with the point of a scalpel a small incision, not more than one-quarter of an inch in length, was made down to the vein of either donor or recipient; it was immaterial which arm one took first; then with the forceps the exposed vein was delivered and encircled with zero plain catgut distally and proximally. That manipulation being finished, the same procedure was carried out on the other subject. The tourniquet was now applied to the donor's arm to compress the veins slightly, not to interfere with the arterial circulation, however, and using the catgut ligatures as tractors the vein was elevated and an opening large enough to admit the needle or cannula made in it with the scalpel; the ligatures were then tied. While the assistant held his fingers over the end of the cannula to prevent the escape of blood, the operator inserted the remaining needle or cannula in the vein of the donor so the point was toward the hand. By working rapidly these details took very little time. The syringe was then applied to the donor's cannula needle, while the donor opened and closed his fist at the operator's command, this latter maneuver facilitating the filling of the syringe, which when filled was detached. The assistant immediately placed his finger over the cannula to prevent loss of blood and at the same time released his finger from the opening in the cannula of the recipient, while the operator attached the syringe and emptied it into the recipient. This maneuver of aspiration and injection, was kept up continuously until the piston of the syringe began to work hard; this syringe was then discarded and the second syringe used in the same way without interruption. In the meantime the previously used syringe was being washed in cold saline and lubricated with oil ready for future use, if necessary. With a good donor, the speaker said he had given as much as 500 c.c. with one syringe. While it was not really necessary, he had used for years small pieces of rubber tubing about 1½ inches in length, between syringe and cannula, the advantages thereby attained being that the assistant could easily compress either tubing at the proper moment without bringing his finger in contact with the blood stream or disturbing the position of the cannula. Legitimate criticism would arise as to the necessity of making an incision in the vein; the writer was cognizant of the fact that the cannula could often be introduced into the vein without previous incision, but with the latter method one often failed to enter the vein properly, and hematoma occurred, clotting took place, and after losing much valuable time, incision was at last resorted to. The advantages of the incision were that there were no attempts at repeated punctures to enter the veins, causing annoyance and embarrassment to the operator and much pain and uneasiness to the subjects. The disadvantage claimed was that one destroyed the vein for future use, but the speaker had often used the same vein by entering the recipient's vein a little higher and the donor's vein at a little lower level than that of previous incisions. Furthermore, there were numerous other veins in this region that could be utilized. There was no pain or distress attached to the operation, unless one worked too rapidly, then the recipient complained of inability to breathe or began to cough; there was a feeling of warmth and a few had complained of backache. When sufficient blood had been given the recipient, the can-

nulae were removed from the veins and a small strip of sterile adhesive plaster was sufficient to coapt the ends of the incision, or one plain catgut suture would answer the same purpose. The operation of blood transfusion was a life-saving procedure and one which in an emergency every surgeon should be prepared to perform with the same facility and ease as he was prepared to do a tracheotomy. This method eliminated costly and unnecessary apparatus and would never fail in competent hands. In closing, the speaker said he wished again to emphasize the advantages of minimizing the use of special instruments and apparatus and thereby at the same time getting the maximum results.

Dr. RICHARD LEWISOHN discussed the technique of blood transfusion. He stated that there was hardly a subject in modern medicine whose development was as purely American in every detail as that of blood transfusion. He traced the important steps in the improvement in the technique of transfusion that had been made in this country, which showed that in the short period of about fifteen years the technique of blood transfusion had been simplified to such a degree that it was now one of the simplest and easiest methods in the armamentarium of the physician. Dr. LewisoHN gave a brief review of the different so-called indirect methods of blood transfusion now in use. The direct methods (artery to vein anastomosis or vein to vein anastomosis, either by direct suture or by the use of some ingenious apparatus as, for instance, the Elsberg cannula) were of historic interest only. They were practically out of use at the present time owing to the difficulties of the technique and the time required for their performance. The indirect methods might be classified in a general way in four groups: (1) The Lindemann syringe cannula method; (2) the stop-cock and valve methods of Unger, Miller, and others; (3) the use of paraffined glass tubes, as originally advocated by Kimpton and Brown, and later slightly improved by Percy and Vincent, and (4) the sodium citrate method. These four groups of indirect methods of blood transfusion were comparatively simple and could be used with safety. There could be no doubt that the sodium citrate method was by far the most popular of these methods. This was explained by the fact that the technique of the sodium citrate method was much more simple than any of the other methods which he had just described. The chills which had been mentioned as more frequent with the citrate method, though unpleasant for the patient, were harmless and did not interfere with the clinical effects of the transfusion. According to the speaker's personal observation in about 500 cases of different diseases, the citrate method was just as effectual as any other method in any pathological condition. It was only fair, however, to state that some clinicians preferred the uncitrated blood when they were dealing with diseases of the blood, such as pernicious anemia, hemophilia, etc. The great efficiency of the sodium citrate method of blood transfusion in the treatment of hemorrhage and shock was best shown by the fact that this method was adopted as the method of choice by the A. E. F. in the recent war.

Dr. HAROLD HAYS said that in attempting to discuss the subject of blood transfusion he felt like an amateur, and his only reason for doing so was because he probably represented the large majority of men present tonight. He had had the opportunity of seeing the various methods used, the Lindemann, the LewisoHN or citrate method, the Unger method, etc. When Lindemann was doing his work most of us had an idea that blood transfusion was an especially difficult and technical procedure. Now he could see that it was something quite different. The technique of the procedure itself was very simple, but it was absolutely necessary to select the proper donor. Blood transfusion had proven itself most valuable in stopping hemorrhage and in sepsis from sinus thrombosis and in thrombophlebitis. Though all methods might be available in cases of hemorrhage, the citrate method was probably the simplest and easiest. This was undoubtedly true, for this method had been selected and employed in thousands of cases abroad in the A. E. F. in preference to other methods. Citrated blood ready for transfusion had been kept at the base hospitals for periods varying from four to six weeks before it was taken to the front

and used, and it was shown that it could be perfectly preserved and successfully used at the end of this time. It had been shown that it was a great advantage to have this citrated blood available and to be sure that it was from the proper donor. It was stated that there were cases of sinus thrombosis with positive blood cultures in which transfusion was all that was necessary to eliminate the bacteria from the blood. He, however, would hesitate to have a patient transfused without first operating upon the sinus and removing the focus of infection, for even with the bacteria eliminated there was a possibility that a clot of blood might form, which later on would break down and cause trouble. However, there were cases of sinus thrombosis in which the patient did not do well even though the bacteria were eliminated from the blood. If there was severe sepsis an operation should be done for sinus thrombosis and a ligation made of the jugular vein; then if a blood transfusion was done the results would be so marked within twenty-four hours that there could be no doubt that transfusion was the ideal method for restoring vitality. There were various ways of treating the constitutional condition following infection which had lowered the vitality, but blood transfusion was a quick and effective method and he did not see why it should not be applied in constitutional conditions with lowered vitality. As the result of advances in our surgical and pathological knowledge blood transfusion had come to where no one need hesitate to use it whether in hemorrhage or sepsis or to counteract lowered vitality, where it was certain to give quicker and more satisfactory results than were obtained by other recuperative methods.

Dr. CHARLES GORDON HEYD asserted that transfusion was no longer a question of technique of operator, or of form of apparatus. It had become such an essentially simple procedure that any physician who gave salvarsan or who was capable of giving intravenous saline infusion was also capable of performing a transfusion. The widespread acceptance of transfusion was due to the fact that in its present form it was an operation devoid of danger, of the utmost simplicity, and requiring no elaborate preparation or paraphernalia. Looking at transfusion in its broadest aspect we had essentially an homologous transplantation of living tissue. The transfusion of blood subserved three main purposes—First, a mechanical function when it replaced (volume for volume) oxygen-carrying fluid in acute hemorrhage; secondly, the chemical function where it stimulated blood forming organs and provided some chemical stimulation for the proper or better functioning of the body, as in the pernicious and secondary anemias; and thirdly, a biotic function where it gave to the recipient some living stimulation, hence the value of transfusion in toxic and infective conditions—for example, in prolonged, suppurative processes. It seemed that there was a definite time for doing a transfusion. It was unfortunately true that transfusion was often reserved until too late or was done for conditions where there was no possible hope of any benefit. He had observed the activation of a gastric hemorrhage following a transfusion and become careful about transfusing immediately upon the cessation of the bleeding. It might be accepted, however, as a general proposition, that any internal hemorrhage should receive immediate attention upon its first appearance and its cause and possibilities accurately determined, for with a transfusion of moderate amount the blood pressure was not materially raised and the increasing agglutinating power given to the recipient more than offset the possibility of activating the bleeding. He had observed that the blood of different donors acted differently in agglutinating properties, and a hemorrhage that had not been completely arrested by one donor might be promptly arrested upon changing donors. So far as accidents were concerned, with proper group testing he had found them to be practically non-existent. He had on one occasion given the blood of the wrong group to the recipient and had been quite surprised to have no untoward results. There was a group of cases that gave some apprehension in which with normal laboratory tests there had been a slight degree of hemolysis; for example, in the case of a patient with pernicious anemia a donor was obtained whose blood by test was absolutely compatible with the patient's. A transfusion

was attempted by the syringe method and upon introducing 8 c.c. of the donor's blood into the circulation of the recipient, the patient complained of headache, vertigo, and nausea, and pronounced projectile vomiting occurred with the development of pain in the back and along the spine. The transfusion was stopped and the operation postponed for a future day. Three weeks later another donor was obtained, the hemolysis and agglutination tests were made, and the bloods found to be perfectly compatible. In this case after giving 90 c.c. of blood by the citrate method, a pronounced picture of hemolysis occurred and again transfusion was stopped. About a month later the operation was repeated, and this time about 450 c.c. of citrated blood was transfused. The patient was returned to the ward in excellent condition. That afternoon she had a rather pronounced chill, temperature 104° F., respirations 30, pulse almost imperceptible, skin cold and clammy, and passed bloody urine. She remained in desperate condition for about two days and then slowly improved. The patient had a previous subicteroid tint which was heightened during the two days succeeding the transfusion. Apparently there was some peculiar chemical property in her blood, due probably to the toxic process that might have been the underlying factor in her pernicious anemia, which was responsible for the hemolysis. So far as blood transfusion was concerned he had yet to see a case of acute sepsis that had in any way been materially benefited by transfusion. On the contrary, he believed that some cases had been made worse. In chronic sepsis—chronic osteomyelitis, chronic bone disease, chronic renal suppuration—he had observed the most marked benefit by serial transfusions. In a chronic *Streptococcus viridans* septicemia, by using an immune donor's blood, he had felt that better results were obtained than with blood from an ordinary donor. He had observed in cholemia or the intense jaundice of obstructive conditions of the common duct that a single transfusion before operation was of much more value than when given after operation, and it had always been a point with him to reduce the patient's coagulation time to seven minutes or less by repeated transfusions. He had not hesitated to give transfusion without preliminary laboratory tests, as he felt that the inaugural symptoms of hemolysis were so distinct that the blood transfusions could be terminated sufficiently early to prevent a mortality from hemolysis. The conclusions that he had come to were: "(1) Transfuse early. (2) Transfuse in moderate amounts, not massive doses. (3) When in doubt transfuse."

Dr. E. LIBMAN said that it might be of interest to know that Dr. Ottenberg had played an important role in the history of blood transfusion. When an interne at the Lenox Hill Hospital he had performed two transfusions with a cannula which he had devised. Had he published his work at that time he would have been considered one of the pioneers in this field. Dr. Libman agreed with Dr. Lewisohn that the credit for developing and perfecting practical methods for blood transfusion belonged to America. He thought, however, that a little credit was due to South America because of the work Dr. Agote had begun in connection with the question of citrate transfusion. With reference to selecting donors, Dr. Libman said that when simply picking a donor according to his group without actually testing his blood with the blood of the patient, reactions might occur. This held particularly true in cases of carcinoma, anemias or fevers. Furthermore, there were other points besides hemolysis that came into consideration. It was important to examine the donor from head to foot, for it was possible that the Wassermann might be negative and the patient have a chancre. There should be a contract between the donor and the family of the recipient. As to the value of transfusion in acute hemorrhage there was no doubt. In secondary anemia transfusion was of value even though the patient would eventually recover without it. Such patients would recover much more rapidly with transfusion. Hospitals objected to the expense of blood transfusion in cases of pernicious anemia and secondary anemia—unless the secondary anemia were very profound. They did not realize that when transfusions were done in such cases the time spent in the hospital was much decreased, and the hospital actually saved money. As for the anemias which were characterized

by having an index over 1 (the so-called hyperchromic type of anemia), there were other conditions besides the so-called pernicious anemia. Dr. Libman said that he did not have sufficient experience to give an opinion concerning the ultimate results of transfusions performed for pernicious anemia due to syphilis. In cases of the severe form of anemia in pregnancy, transfusion was of considerable value. In such cases, although nucleated erythrocytes and macrocytes were found, and the index was over 0.1, complete recovery could occur. In cases of multiple bone tumor, the index might be nearly 1 or above 1. The clinical picture might resemble that of a true pernicious anemia. In such cases transfusion had no results. In so-called essential or primary anemia the results were very variable. Minot and Lee had made a study of this subject, which was probably more thorough than any other study. From their observations it appeared that in the type of pernicious anemia which had a tendency to have remissions, the results were better than in the type in which remissions did not occur. Dr. Libman said that he had had an extensive experience with transfusion in cases of primary anemia and some of the results had been quite remarkable, very long remissions at times being obtained. Not all the symptoms were removed, but only those due to anemia, such as fever, gastric symptoms, asthenia, sleeplessness, and cardiac weakness. The cases in which transfusion was indicated were those having a hemoglobin of 60 per cent. or less. If two transfusions did not give results it was not advisable to continue them. It had been found that sometimes transfusion gave a better result after a splenectomy had been performed. Dr. Libman had himself made some observations. His usual method was to use transfusions first, and when they no longer gave a definite result, to have a splenectomy performed, if there were no contraindications to the procedure. After splenectomy had been performed, transfusions were again used as long as they gave a definite result. Dr. Libman had found that the gastric symptoms in cases of primary anemia were often relieved when the hemoglobin was raised by means of transfusions, even though the hydrochloric acid never returned. In cases of leucemia transfusion had acted as a means of palliation for gastric symptoms due to an accompanying severe anemia. In Hodgkin's disease, and cases of neoplasm in which a severe anemia was present and it was intended to use radium or intensive x-ray treatment, it had been found wise to improve the condition of the patient by a preliminary transfusion. In infections, transfusion simply helped to strengthen the patient and gave him a better chance to find the infection. As regards the use of transfusion for the cure of mastoid disease and sinus thrombosis, it was much more important to deal surgically with the local disease and to use transfusions only if the patient became debilitated or if an anemia had developed. If a lateral sinus thrombosis was properly surgically dealt with, the bacteria as a rule disappeared from the blood very promptly and there was no occasion to use transfusions for a bactericidal purpose which the blood and the organs of the patient were already subserving.

Dr. EDWARD W. PETERSON said that blood as a therapeutic agent was used (1) as a tissue transplant in simple hemorrhage; (2) for its hemostatic powers in the control of various types of pathological hemorrhage; (3) as a stimulant to the blood making system in anemia, both primary and secondary; and (4) in selected instances of toxemia and sepsis it might exert feeble antitoxic and bactericidal properties. Given as a tissue transplant in acute post-hemorrhagic anemia it acted as a specific and would immediately resuscitate a dying patient. In pathological hemorrhage it was the most valuable agent at our command and would often save lives after the failure of all other measures. Likewise in treating both primary and secondary anemia, blood had proved to be our best hematopoietic stimulant. He agreed with Doctors Libman and Heyd that blood transfusion accomplished but little in overcoming acute sepsis. He felt that transfusion was indicated in selected instances, after the sepsis had exhausted itself, to restore the vitality of the patient. It often did good in the low-grade forms of chronic sepsis. His belief was that the benefit derived from blood in these cases was due, not so much to the antitoxic or bacteri-

cidal powers, as to its action in overcoming the associated anemia. Dr. Peterson stated that he had performed a large number of blood transfusions, using both unmodified and citrated blood. At one time he felt that the results from the two methods were about equal. At present, however, he wished to state his preference for unmodified blood in the treatment of anemia not due to hemorrhage, and in the management of the various types of pathological bleeding.

THE PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held December 8, 1920.

THE PRESIDENT, DR. HERMAN B. ALLYN, IN THE CHAIR.
Symposium on Control of Tuberculosis in Pennsylvania.

Summary of the Work of the Philadelphia Health Council and Tuberculosis Committee.—Dr. JOHN BLAIR SPENCER contributed this paper in which it was stated that a group of public spirited doctors and laymen had met in Philadelphia in 1892 and organized the Pa. Society for the Prevention of Tuberculosis, the first organization of its kind. Out of this Society had grown the present Philadelphia Health Council and Tuberculosis Committee and a great nation wide organization, the National Tuberculosis Association, with 1500 branches throughout the country. The fight against tuberculosis had met with increasing public spirit. In 1904 the total sum of money spent throughout the country in the fight against tuberculosis was \$100. The returns on the national seal sale in 1919 amounted to more than four and a half millions of dollars. The impressive period of childhood was the logical time to establish good health habits, so that greater emphasis was put on public health work among children. This work was done both in school and in organized child groups outside of school. The work in schools included: helping the teachers to popularize the teaching of health habits, talks to emphasize the value of keeping the health rules, motion pictures, plays and pageants, posters, exhibits, weighing and measuring the school children and nutrition work with the open air and the open window classes. Talks emphasizing the simple principles of health were given by staff members either at the morning assemblies or to separate class rooms. Because of the large number of children so much under weight, it was deemed necessary to establish a home where they could be built up and get intensive health education. A building at Brown's Farms had been given for this use. During August and September 141 children received from 1 to 3 weeks at the farm. Wholesome food with plenty of milk, play in the big yard, and plenty of rest made possible a gain of from 5 to 10 pounds each. A permanent home for undernourished and anemic children had grown from this. Lectures and talks upon health principles were given by the staff either separately or in a series of clubs, fraternal orders, industrial plants, welfare organizations and in church. Motion pictures depicting health principles were often shown in industrial plants at the noon hour.

The Educational Campaign Against Tuberculosis in Pennsylvania.—Mr. ARTHUR M. DEWEES said that we knew that 30 years ago the fundamental facts regarding the cause and development of tuberculosis had just come to light. The Pennsylvania Society, therefore, undertook to cultivate absolutely unbroken ground when it took up the task of bringing the known facts to the knowledge of the general public. During the early years of its history the Society had worked in a quiet, but persistent way. Papers on various phases of the tuberculosis problem had been prepared, read, and published. From time to time literature had been issued for popular distribution. Opportunities had been sought for presenting the subject at medical meetings and other occasions. Efforts had been made to arouse health authorities to a sense of their responsibilities in the matter of tuberculosis. At least 15 years ago the activities of the Society had begun to bear fruit in the formation of local tuberculosis organizations in different sections of the State. In most instances these local organizations had had for their object mainly the relief aspect of the tuberculosis

problem. About the same time sanatoria had been established at several points. Many of these organizations were strong, countywide tuberculosis societies, with full-time, paid secretaries, doing their work on a budget basis and in a businesslike way. In many places the local organization was still a committee of a woman's club. It might be said in passing that too much credit could not be given to the women's organizations of the State for the generous interest and the hard work they had put into the fight against tuberculosis. The Pennsylvania Society confined its efforts very largely to a program of education and propaganda. They had endeavored to keep in line with the program for the country outlined by the National Association while at the same time taking into account conditions and needs in their own State.

Dr. JAMES M. ANDERS said that the chief work of this Society was the education of the public in the nature and means of prevention of tuberculosis. As regarded prevention the general fact was recognized that whatever agencies tended to improve the health of the community, tended to lessen the prevalence of tuberculosis by increasing individual resistance to the disease. Hence the modern health crusade carried on throughout the State of Pennsylvania had met with truly remarkable success. There had been two agencies which had never been utilized to the extent to which they rightly deserved, namely, the newspapers and literature more or less suitable for preservation. We knew as physicians that reports in the daily newspapers of scientific facts were often garbled and misleading, but if the subject matter was carefully prepared in advance and the editor was asked to insert it without change, it could often be accomplished. It had been found that the country population suffered but little less from tuberculosis than those living in the densely populated cities and also that they were just as much in need of instruction along the lines of personal hygiene with special reference to tuberculosis as were the densely populated cities and towns. We as physicians well knew that in the great majority of cases of tuberculosis we could trace a new case directly to a former case in the infective stage either in the same household or in the same neighborhood, and, if this were true, then surely when cases of tuberculosis reached the infective stage they should be isolated. He believed that, until this was accomplished in a greater degree than had been done in the past in Pennsylvania and elsewhere, efforts to control the prevalence of tuberculosis would certainly be slow and unsatisfactory. General hospitals should be induced, wherever feasible, to set aside a special ward or room for the reception and treatment of cases of advanced tuberculosis. The Pennsylvania Tuberculosis Society believed that the time had arrived when each county, or group of counties, according to the population should provide an institution for the reception and care of advanced cases of tuberculosis. At the 1920 meeting of the Medical Society of the State of Pennsylvania resolutions endorsing such a bill were passed. It was hoped that every county medical society of the State of Pennsylvania would pass similar resolutions, in which case the resolutions should be forwarded to Dr. Edward Martin, Commissioner of Health, Harrisburg.

What the United States Government Is Doing for the Tuberculous Ex-Soldier.—Dr. DANIEL M. HOYT, U. S. Public Health Service, in Charge of Tuberculosis in Pennsylvania and Delaware, read this paper in which he said that the medical care of the discharged soldier who had been disabled was under the Public Health Service. The country had been divided into 18 Districts. Each was under the direct supervision of a District Supervisor. The 3d District, which included Pennsylvania and Delaware, was the one of immediate interest to us. In every County of these two States there had been appointed one or more physicians, known as Designates. So far as possible, these appointments had been made from the men who had had service in the late war with Germany. There were 135 of these. Besides these designated officers there were about 121 for special examination of the chest. These physicians received a fee of \$5 for examination and a nominal office fee for treatment. The U. S. Public Health Service had not made provision in its Public Health hospitals for all claimants requiring hospital care. In

this district the Government had made contracts with practically all of the civil tuberculosis hospitals. The State Tuberculosis Sanatoria were, generally speaking, excellent for the ex-soldiers. It was unfortunate that we were unable to send our cases direct to these sanatoria instead of having their applications held up 6 to 7 weeks to go through the dispensaries. All the other civil institutions accepted the cases direct. The ex-soldier suffering from suspected tuberculosis was handled as follows: The man was discharged from the service and if he had, or thought he had, a disability he went to the nearest Designate with a copy of his discharge and an examination was made. The Designate made a diagnosis if possible, stated whether or not the man's condition was due to the service, about what he considered the degree of disability, whether or not training was feasible, whether he should be treated as an out-patient or admitted to the hospital. His report was sent to the central office; if satisfactory, transportation was furnished the man and he was sent to the hospital. If the diagnosis was indefinite, the man was referred to the tuberculosis specialist in his vicinity. The diagnosis of pulmonary tuberculosis in the ex-soldier must be backed up by all possible evidence because such a diagnosis made the man dependent upon the Government for life. The diagnosis was difficult because almost every ex-soldier who had seen foreign service claimed that he had been gassed. The number of cases suffering from pulmonary disease due to irritating gases was extremely small, and, furthermore, it was uncommon for tuberculosis to follow gas inhalation.

Dr. RALPH M. TYSON said that treatment in the homes of claimants was not allowed. They had to be either well enough to report to the dispensary or to the Designate physician's office or accept hospital care. Cases that were sent to the various hospitals for study or for treatment were furnished with routine cards of admission. The hospital was asked to send report cards showing the exact date of admission and discharge. They were also asked to furnish copies of the clinical record. Arrangements had been made for ward treatment only. The Public Health Service had contracts with 60 hospitals throughout the state for general medical and surgical cases. In case of emergency the Designate physician could send the man immediately to a hospital. There were approximately 450 tuberculous cases in hospitals in this district. It had been found that, after arrangements have been made and a man furnished with transportation and card of admission to a sanatorium or hospital, in about 15 per cent of cases he failed to report or to notify the district office or the hospital. Long trips to the southwest, to Arizona or New Mexico, were not looked upon with favor as they were usually ill-advised. The fact that the men were fighting for their lives was never lost sight of by the Public Health Service. The men wanted and deserved the very best and as far as possible the Public Health Service was supplying it.

Dr. CHARLES S. AITKEN said that in his work in the Chest Examining Room at the central office men were dealt with whose pulmonary lesions were influenced by the diseases and wounds incident to war. It had to be borne in mind that these men were seeking compensation and their symptomatology might be augmented by them at times. He had found influenza and pneumonia predisposing causes of tuberculosis, and, although nearly all the men gave a definite history of having been gassed, very few of these cases proved to be tuberculous. He believed that a history of these chest cases was just as important as in any other condition. Every good physician should be able to differentiate between the history given by a gas case and the history given by a tuberculous case. In regard to basal conditions it had been found that these were usually pneumonic, post-influenzal, or luetic and the tuberculous lesions were usually found in the apices.

Measures for the Control of Tuberculosis in Cattle.—Dr. CLARENCE J. MARSHALL said that on Jan. 1, 1919, there had been supposed to be 979,000 dairy cattle in Pennsylvania, of which 10 per cent were tuberculous. Pennsylvania had begun an active campaign to control tuberculosis of cattle in 1896. The work had been continued since that time as rapidly as funds, authority

and assistance would permit. From 1896 to 1919, 272,895 head of cattle had been tested with tuberculin under State supervision, of which number 32,392 failed to pass the test. Tuberculin testing had met with considerable opposition at first. The objections were that it was thought it would produce the disease in uninfected animals, that it would make them more susceptible to infection, that it would cause abortion or favor its spread in a herd, that animals free from the disease would react and that it would not select all the infected animals in a herd. All of these objections had proven incorrect. Although tuberculin was not infallible, it was of the greatest importance in detecting tuberculosis. It was considered accurate in about 95 per cent. The State had never attempted to force herd owners to submit to the test. Certain local boards of health had been rather insistent at times that the State should help them to force a test on all animals producing milk for the community, but this the State had never been able or willing to do. The best progress had been made in cooperation with the owner. Practically all testing had been done at the request of the owner after he had been informed of the disagreeable conditions that might arise. Animals that reacted to the test were slaughtered under State or Federal supervision, the owner being entitled to all receipts from the hide, carcass, and offal. In addition to this there was an indemnity provided by law from the Federal and the State Government. The total number of animals tested in the past 25 years was little more than one-fourth the number of dairy cows in the State. Each animal should be examined and tested at least once a year if the disease was to be controlled. However, it was physically and financially impracticable at present to undertake this task on so large a scale. The Bang system of controlling tuberculosis, so successful in Denmark, had not proven popular in America. Much tuberculosis had been spread by public creameries, skimming stations, etc. Swine and calves that were fed on the refuse from such stations were usually heavily infected with tuberculosis. The State had tried in various ways to prevent such infection and energetic effort had been made to have such products pasteurized. There had been considerable improvement in the past few years in the way of more sanitary housing conditions for live stock. The value of sunlight, ventilation and drainage was much more appreciated than in former times. It was pretty well understood that tuberculosis in animals was communicable from animal to animal and that, if it was allowed to run unchecked in a herd, it would eventually render a large percentage of the animals unprofitable and worthless. According to the best authorities of the present day it was claimed that 10 per cent. of the tuberculosis in the human family could be traced to bovine origin. If this were true, the matter should be of vast importance to physicians and sanitarians.

Some Aspects of the Tuberculous Problem in Europe.

Dr. PAUL A. LEWIS said that since the armistice the population of Vienna had been in a half starved condition and was well on the way to extermination. This would have resulted if it had not been for outside efforts, especially those of the American Relief Administration and the English Society of Friends. What one saw today was deprivation of food and partial starvation. The effort to remedy conditions was exerted chiefly in the direction of the children and a fairly successful effort was being made to feed all the children in Austria who were not otherwise provided for. He said that he could assure his hearers that conditions were really as described. Well over 99 per cent. of what actually landed there in terms of food as measured in money was actually given to the people—it was not only given to the people to be eaten, but it was eaten in a reasonably palatable form. This relief work was saving hundreds of thousands of people from eventual tuberculosis. A set of records of the children was kept detailing the weight, the height, and a statement of the general condition. If Vienna survived, these records would become a part of the vital statistics of the community for the next generation and we should have some definite data as to the consequence on tuberculosis and perhaps other diseases. In Liverpool and Edinburgh examples of the

finest sort of antituberculosis work, which in some respects could serve as models for work here, were found.

Dr. WALTER S. CORNELL said that in 250,000 school children our weakest spot was in the determination of the state of nutrition and possible tuberculous conditions. While there were 72 inspectors, not more than 5 minutes could be given to each examination. They found that they had very good records of eye strain and nose and throat troubles, but not of anywhere near the number of poor nutrition cases that they knew existed. About 300 children, about 60 of whom were tuberculous, had been gathered into special classes. The cost for food was \$12,000 annually. If tuberculosis was viewed in the proper light, a more determined effort would be made to eradicate the carriers of the disease. If we could get rid of the spitting tuberculous patients and tuberculous houses and get rooms cleaned where people die of tuberculosis so that they could not infect their successors we would have accomplished something worth while. He did not think that we would get much farther than we are now unless we made up our mind to buckle down and do these things.

Dr. WILLIAM DUFFIELD ROBINSON said he regretted that those who had made up this program had not introduced the work of the Department of Health of the State of Pennsylvania. We ought to remember that the State had 3 sanatoria where they were treating 2,200 patients a month and there were about 87 clinics where at least 8,200 to 8,500 a month were being treated. If we were going to have this matter properly presented, the work of this State should have been given some prominence.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

MEDICAL COUNCIL OF CANADA.

October, 1919.

HYGIENE AND STATE MEDICINE.

1. State the measures which you would adopt to prevent the spread of typhoid fever. How should the dejecta from a typhoid patient be disinfected and what is the best disinfectant to be used?

2. Outline a system of disposal of wastes suitable for a large village and a city.

3. Describe the means by which heat in its various forms may be used for disinfection. Name three chemical agents commonly used in disinfection and state their limitations.

4. What are the preventive measures necessary to be taken against the spread of tuberculosis?

5. How may the water of a superficial well become dangerous to health? What means would you advise to be taken in order to render the water safe?

6. Discuss fully the value of purification of water by the hypochlorite of lime method and by filtration.

PATHOLOGY AND BACTERIOLOGY.

1. Discuss fully the mechanism at work in the production of edema. Describe the pathological changes present in this condition. What are the results?

2. Define "cough" and "dyspnea." State what you know as to their causes, clinical forms, and evolution.

3. Define carcinoma, sarcoma, infective granuloma.

4. Summarize the principal gross lesions found in the intestines in the following diseases: (a) typhoid fever; (b) tuberculosis; (c) amebic dysentery; (d) bacillary dysentery.

5. What are the morbid changes, macroscopical and histological, met with in the bronchi, lungs, and pleural cavities during the course of "la grippe"?

6. Give in detail the morphological, cultural, and pathogenic properties of (a) meningococcus; (b) *Diplococcus pneumoniae*; (c) gonococcus.

OBSTETRICS AND GYNECOLOGY.

1. Describe the management of labor in a case of twin pregnancy.

2. What are the difficulties which may develop in the

course of labor in which there is a simple breech presentation?

3. A woman in the thirty-seventh week of her fourth pregnancy complains of headache and constipation. Describe your examination of the case and the treatment you would advise.

4. How would you recognize a shoulder presentation in a woman in labor? Under what circumstances in such a case would internal version be contraindicated?

5. Note briefly the difference between the normal and abnormal vaginal secretions and enumerate the various pathological vaginal discharges, giving their diagnostic significance.

6. What are the causes of pruritus vulvæ?

ANSWERS.

HYGIENE AND STATE MEDICINE.

1. *To prevent the spread of typhoid fever:* Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleaned, and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put in water or other drink or food. The dejecta should be disinfected by means of chlorinated lime. About a pint of solution of chlorinated lime should be placed in the vessel in which the dejecta are to be received; the contents of the vessel should be well stirred, and should be allowed to stand for from one to two hours before being emptied.

2. *DISPOSAL OF WASTES. In a village:* Kitchen drainage should be collected in a pail and then thrown into the yard, away from the house, and in a different spot on each occasion, so that the fluid may sink into the soil and not lie on the surface. *Garbage* should be buried or burned. *Privy contents* may be buried, or sometimes (with care) used as fertilizers. *In a city:* The kitchen drainage and human excretions will be carried off by the sewage arrangements; the garbage should be collected and burned.

3. *Heat may be used as a disinfectant in the following ways:* By boiling; by steam; by dry heat; by burning. *Three chemical disinfectants:* (1) *Formaldehyde* does not damage fabrics or metals, but it only disinfects the surface as a rule; it does not penetrate, does not kill spores of anthrax, and is not an insecticide. (2) *Sulphur dioxide* bleaches colored fabrics, attacks metals, and rots or weakens fabrics. It is not a very good germicide but will kill insects. (3) *Mercury bichloride* kills germs and spores, but is very poisonous; it forms insoluble and non-poisonous compounds with albuminous matter, and it corrodes metals.

4. "The preventive measures which may be taken to reduce tuberculosis may be summarized as follows: (1) The compulsory notification of phthisis. (2) The removal of those conditions of domicile and of occupation which are known to promote the incidence of the disease, including the regulation of certain dusty trades. (3) The diffusion of knowledge (by medical men, leaflets, etc.) regarding the nature and modes of spread of the disease, and the precautions which should be taken in order to prevent its extension. (4) The testing of sputum and other suspected discharges, and of milk, meat, etc., supposed to be tuberculous—reports to be furnished free of charge. (5) Local authorities to undertake, without charge, the disinfection of houses recently occupied by phthisical persons. (6) The establishment of sanatoria and isolation accommodation for the cure of phthisical patients, and the isolation of those who are a distinct source of danger to fellow lodgers or workers. (7) The enforcement of measures against spitting in public conveyances and in places of public resort. (8) The efficient sanitary supervision of dairy farms, dairies, and milkshops. The periodical veterinary inspection and testing (by tuberculin) of milch cows, and the slaughter of tuberculous animals.

The prohibition of the sale of milk of cows affected with tuberculosis. (9) The proper inspection of meat in public abattoirs, and the adoption of due precautions for the control of imported meat and milk."—(Parkes' *Practical Hygiene*.)

5. *Superficial wells* may become polluted from organic matter from the soil, and from sewage. The water may be rendered safe by being boiled. Various chemical methods have also been devised for the purification of water, such as chlorine, chlorinated limes, ozone, potassium permanganate, iron, alum, and copper sulphate.

6. *Purification of water by the hypochlorite of lime method*: "The purification of water by means of a little bleaching powder is cheap, reliable, efficient, harmless, and easy of application, all of which make it an attractive method. When added in proper quantities it leaves no undesirable chemical substance in the water. It must, however, be remembered that bleaching powder in no sense clarifies a water. In fact, turbidity interferes with its action to a certain extent. It cannot, therefore, render a turbid supply entirely satisfactory. Furthermore, while chlorinated lime in such small quantities will kill bacteria it will not purify organic matter nor cure discoloration, nor take away the unpleasant smells which raw waters often contain."

Filtration: "Mechanical filtration affords a comparatively cheap method of supplying a clean-looking water from a very turbid source. . . . Mechanical filters, when properly manipulated, will take out from 95 to 99 per cent. of the bacteria contained in the raw water. The bacterial filtration, however, is not as constant and uniformly high as that obtained by slow sand filtration."—(From Rosenau's *Preventive Medicine and Hygiene*.)

PATHOLOGY AND BACTERIOLOGY.

1. **EDEMA.** According to Thayer, "six factors enter into the production of edema, usually more than one acting at a time, viz., positive pressure in the vessels (in proportion as it rises), permeability of the vessel wall, osmosis from excess of salts outside the vessel as seen in the action of a saline laxative, selective action of the endothelium, variations in the blood plasma and obstructed onflow in the lymph channels."

Pathologic anatomy: "Edema may take various forms according to its situation. In some cases it is localized, affecting a limited part of the body, as a single organ or member. In other cases it is widespread in the subcutaneous tissues and skin, when the term *anasarca* is applied. It may occur in the serous cavities in the form of serous transudates (hydrothorax, ascites, hydropericardium, etc.). The liquid itself varies in character according to the cause. In the pure transudates due to increased filtration the liquid is watery, low in specific gravity (below 1016), and comparatively poor in blood corpuscles and albuminous constituents. In cases in which disease of the vessel walls has played a large part in the causation, especially in the inflammatory edemas, the liquid is more dense and contains more corpuscles and albuminous bodies. The transudate first occupies the lymph spaces or interstices of the tissues, causing a more or less uniform swelling and boggy texture. The tissue pits on pressure, and on section more or less abundant liquid exudes. The solid organs (kidneys, liver) are lighter in color, less dense, and more moist on section than normal; but the appearances of edema are here less characteristic than in the subcutaneous or submucous tissues, or in the softer organs like the lungs and brain. Microscopically the tissue elements are seen to be pushed apart by the transudate, and in some cases the cells themselves may be diseased."

Results of edema: "The function of edematous parts is necessarily impaired. Sometimes serious consequences ensue, as in the case of edema of the epiglottis, the lungs, or the brain. Secondary changes may occur in parts the seat of continued edema. Among these are various degenerations of the cells and a productive change in the connective tissues. The latter is well illustrated in the sclerotic change in the subcutaneous tissues of long-standing dropsy, elephantiasis, etc."—(Stengel's *Pathology*.)

2. *Cough* is a sudden and violent expulsion of air following a deep inspiration; the expiration is obstructed by the closure of the glottis.

"Cough may be brought about by reflex irritation, hysteria, or direct irritation as the result of the inhalation of irritant vapors or dust, or the presence of foreign bodies; but is usually due to inflammatory conditions of the pharynx, larynx, trachea, bronchi, or lungs. In the early stages of inflammation of any portion of the respiratory tract, and when excited reflexly, it occurs without expectoration and is termed *dry cough*. With the occurrence of exudation and outpouring of serum, blood, etc., the cough is attended by expectoration and is called *moist cough*. Laryngeal conditions, whooping cough, hysteria, and recurrent laryngeal nerve irritation are attended by a cough having a metallic ringing intonation. This is laryngeal or croupy cough."

"*Dyspnea* is the term used to denote difficult or impaired breathing. It may be inspiratory, expiratory, or both; and there may be an increase in frequency, or depth, or both, of the respirations. It is attended by varying degrees of distress and when its severity requires the patient to sit up constantly it is called *orthopnea*. Dyspnea may be due to obstruction of the air passages, pressure upon the respiratory system from without by tumors, and distention of abdomen, diseases of the lungs and pleura, heart disease, asthma, anemia, or paralysis of muscles of respiration as the result of hemorrhage, tumors, or degeneration of the respiratory center in the medulla or toxic agents in the blood. It may be *inspiratory* when it results from obstruction as in foreign bodies in the larynx or trachea, or it may be *expiratory* as in emphysema, or bronchial asthma. A combination is the more frequent condition. In all forms of dyspnea it is important to determine whether the shortness of breath bears any relation to exertion. Dyspnea independent of exertion is a serious condition and is symptomatic of severe cardiac and pulmonary disease. Dyspnea dependent upon exertion is less serious and is observed in health, simple debility, anemia, obesity and somewhat moderate cardiac debility."

The rate of respiration varies greatly in dyspnea. Dyspnea with slow or normal breathing is observed in diabetic coma, and again the breathing may be slow and stertorous as in coma of central origin. Rapid respiration occurs in inflammatory pulmonary disease, pleurisy, painful affections of the chest muscles, heart disease, fever, hysteria, toxic conditions affecting the respiratory centers, anemia, and morbid conditions at the base of the brain. Irregularity in the respiratory rate in dyspnea may also be observed. *Cheyne-Stokes breathing* is the term applied to this condition when the respirations gradually increase in rapidity and depth until a climax is reached, after which there is a period of apnea or absence of breathing. The paroxysm is then repeated. It is a serious indication and may be observed in meningitis, apoplexy, cerebral tumor, fatty degeneration of the heart, uremia, and similar conditions. Dyspnea may be constant or paroxysmal. Constant dyspnea is always due to a persistence of its cause. Paroxysmal dyspnea is seen in asthma and cardiac affections. It may follow exertion in various central or reflex conditions. It is most marked at night."—(Hughes' *Practice of Medicine*.)

3. *Carcinoma* is an epithelial tumor of a malignant type, in which the epithelial cells grow in an independent and atypical manner in a connective tissue stroma.

Sarcoma is a connective tissue tumor of a malignant type; the cells are variable, and the stroma less noticeable than in adult connective tissue.

Infective granuloma is a term applied to a group of diseases including tuberculosis, lupus, leprosy, syphilis, glanders, actinomycosis and rhinoscleroma. The lesions show some slight resemblance to a tumor.

4. *The intestines in typhoid fever*: "Principally inflammation of the lymphoid tissue of the lower portion of the ileum, with more or less catarrh throughout the bowels. Peyer's patches—first week.—Are swollen through infiltration of leucocytes, the surfaces raised and fawn-colored—the infiltration involves the submucous coat. The lesions are most numerous at the lower end of the ileum. Second week.—The surface becomes abraded; sloughs form which are often bile-stained. Third week.—Sloughs come away, leaving ulcerating surfaces. Typical typhoid ulcers are thus formed. A

few solitary glands undergo the same process. At the end of the week the ulcers begin to granulate, but healing is usually slow. Mesenteric glands may undergo the same changes, but more often become swollen, red, and tender only, or break down into cheesy masses. The ulcer of typhoid fever—(1) Lies in the longitudinal axis; (2) edges—thin, undermined; (3) situation—last yard of the ileum; the ulcers are most numerous near the ileo-colic valve. The distribution may be more widespread. Its base may be formed of—(1) Submucous coat; (2) muscular tissue, or (3) peritoneum only. The ulcers show a tendency to perforate, but do not cause constriction after they heal." (Wheeler and Jack's *Practice of Medicine*.)

"*Tuberculous ulceration* affects principally the ileum, cecum, and colon. The ulcers contrast with those of enteric fever in that they are irregular in outline, with their long diameter in the circumference, not the axis, of the bowel, and their edges are infiltrated and undermined. They involve the submucous and muscular coats, and may perforate. Cicatrization may cause a single or multiple stricture of the bowel. In the ileocecal region tuberculosis may cause a chronic hyperplasia, sometimes involving the appendix." (Wheeler and Jack's *Practice of Medicine*.)

"In *amebic dysentery* the lesions are chiefly seated in the large intestine. They present—(a) small gelatinous swellings of the mucosa, with partial ulceration; (b) necrosis and sloughing of the underlying tissues. The ulcers of amebic dysentery thus have undermined edges. The amebæ are found in the ulcerating mucosa, but more abundantly in the tissues beyond the ulcerated area (submucous or muscular coats), where they set up edema and necrosis. Later, along with the ulcers, cicatrices, leading sometimes to partial stricture, may be found." (Wheeler and Jack's *Handbook of Medicine*.)

"In *acute bacillary dysentery* the principal changes in the intestinal mucous membrane are: (1) Intense hyperemia, the mucosa being swollen, corrugated, and here and there hemorrhagic. (2) Necrosis, and fibrinous exudate, with formation of a pseudo-membrane. (3) Ulceration, at first on the summit of the folds, but extending both deeply and laterally.

"In *chronic bacillary dysentery* the mucosa is thickened and granular, and the whole gut is thickened. There are chronic ulcers with thickened edges, and areas of scar tissue. Consequently there are partial strictures of the bowel, which is dilated above. A typical dysenteric ulcer therefore has the following characters: (1) Site; on the ridges of the large intestine. (2) Edges; irregular and thickened. (3) Base; may be formed of any of the coats. (4) Tendency to contraction on healing. The so-called 'diphtheritic dysentery' is a form in which necrosis is very extensive and the development of pseudo membrane pronounced. In advanced cases the whole mucosa may form 'a black, rotten, friable, charred mass.'" (Wheeler and Jack's *Handbook of Medicine*.)

5. *Pathology of Influenza*: "Inflammation of the trachea and bronchi may be present. In the lungs the typical change is bronchopneumonia, in isolated patches separated by air-holding tissue. The confluence of neighboring areas may resemble croupous pneumonia on superficial examination. On inspection, in the center of the involved lobules grayish-yellow pin-head to pea-sized elevated foci may be seen, surrounded by engorged pulmonary tissue. On pressure, a greenish yellow thick pus may exude from the infiltrated tissue or the cut ends of the bronchi. On microscopic examination, the bronchial epithelium may be found lying free in the lumen, separated from the submucosa. The smaller bronchi may be entirely filled with leucocytes with complete absence of epithelium. The peribronchial connective tissue may likewise be infiltrated with cells. Enormous numbers may crowd the neighboring alveoli for varying distances from the affected bronchi and completely efface the normal pulmonary structure. The cellular character of the exudate is usually very striking, but varying amounts of desquamated epithelium, serum, and fibrin are present. The fibrin, however, is much less abundant than in croupous pneumonia. Great numbers of influenza bacilli are found in and among the pus cells of the bronchi and alveoli in the areas of most marked broncho-pneumonia. They become less numer-

ous as the periphery of the lobular process is approached. In the microscopic sections of influenza pneumonia it is not infrequently noted that the alveolar septa are absent in small areas of most marked cellular infiltration, apparently forming the beginning of small abscesses. In a smaller number the cells in these places may be necrotic, suggesting the impossibility of full restoration to normal. . . . In subacute or more chronic cases an increase of connective tissue may be observed."

6. The meningococcus is a small, non-motile, non-capsulated, non-flagellate coccus; it does not form spores, does not liquefy gelatin, is aerobic, and pathogenic; it appears in diplococcus groups, and may be found within or outside the cells; it stains readily with the ordinary anilin dyes, but is Gram negative. It grows readily upon meat infusions, and especially so on media to which ascitic fluid or blood serum has been added. It grows best at about 35° C. In man, the lesions are most noticeable at the base of the brain; the spinal cord is always affected.

The *Diplococcus pneumoniae* generally occurs in pairs of round or oval cocci, it has a capsule, but no flagella; it is aerobic, and optionally anaerobic; it grows on neutral or slightly alkaline media with blood serum; the best temperature for its growth is about 37° C. It is found (in four strains) in lobar pneumonia; also in bronchopneumonia, and diphtheria.

The gonococcus is a micrococcus occurring in the form of diplococci, of "coffee-bean" shape. They occur outside and inside the epithelial cells in the discharge. It is a facultative anaerobe and grows best at about blood temperature; it has no spores, and is non-motile. It grows best on nutrient agar with blood serum. It is not transmissible to animals. In man, it affects the genital mucous membrane, conjunctiva, and rectal mucous membrane; the gonococcus is also found in endocarditis and septicemia.

OBSTETRICS AND GYNECOLOGY.

1. *Management of Labor in Twin Births*.—The management of labor in twin births differs in no wise essentially from that of ordinary labor, save that, owing to the marked overdistention of the uterus, the pains are likely to occur at long intervals and be inefficient. The cord of the first child should be ligated on the placental as well as the fetal side, owing to the possible existence of a vascular communication between the two placentas. Since the passages are dilated by the birth of the first child, the second birth, except when the first child is undersized, usually is rapid, or, if necessary, may safely be made so.

The delivery of the second child, however, should be left to nature except for cause. Changes in the position of the second child frequently occur during, or just after, the delivery of the first; hence the necessity of making an examination immediately on the birth of the first twin, to detect any abnormality in the position of the second. The fetal heart should be watched, and immediate delivery effected if it becomes abnormal. As the overdistention of the uterus exposes the woman to postpartum hemorrhage, extra care will be needed to secure firm uterine retraction by means of manipulation and by the use, in addition, of ergot and pituitrin.

Interlocking Twins.—This anomaly, which is exceedingly rare, presents two principal varieties:

(a) Both presentations cephalic, both heads offering, one impacted between the head and trunk of the other fetus;

(b) One presentation cephalic, one pelvic, the after-coming head of the breech birth being impacted between the head and trunk of the other fetus.

Management.—If it is not possible to disengage by a combined internal and external manipulation, with the aid of anesthesia and the knee-chest or the Trendelenburg position, the first child may be perforated or decapitated.—(Polak's *Manual of Obstetrics*.)

2. *Difficulties which may develop in the course of labor in a simple breech presentation*.—Pressure on the cord, with asphyxiation of child; premature inspiration on the part of the child; premature or incomplete separation of the placenta; extension of one or both arms; mal-position of one hand behind the head of the child; fractures, dislocations, separation of epiphyses,

trauma to soft parts, and hematoma; rupture of maternal soft parts.

3. *Further examination* should include analysis of the urine, investigating the total quantity voided in each 24 hours, the amount of solids excreted, particularly the amount of urea, the ammonia coefficient, the presence of albumin and casts; the blood pressure, systolic and diastolic; ophthalmoscopic examination, for hemorrhagic retinitis; edema, disturbed nervous system, and disturbed vision are often to be noticed. *Treatment* includes reducing the protein metabolism, eliminating red meats, and in severe cases restricting the patient to a milk diet; plenty of water must be administered; diuretics, diaphoretics, and laxatives are required; hot air baths, or a hot, wet pack may be desirable; colon irrigations are useful; the blood pressure should be reduced by means of chloral or of veratrum viride; if, in spite of treatment, an eclamptic seizure occurs, it may then be necessary to empty the uterus at once.

4. *A shoulder presentation may be recognized during labor*, by feeling some or all of the following features:—The acromion process, the spine of the scapula, the ribs, the head of the humerus, and the clavicle.

Internal version in such a case is contraindicated when the uterus is found to be in a state of tetanic contraction.

5. *The normal vaginal discharge* is a rather thin, opalescent fluid, devoid of viscosity, and sometimes when abundant, forming a white flocculent and curdy matter; it gives a strongly acid reaction, and contains the vagina bacillus and a fungus (which are invariably absent from pathological secretions). There may also be seen a clear viscid discharge, composed principally of mucus; this is the normal cervical discharge, and is usually not seen except on examining with the speculum. *Pathological secretions are:*—

(a) A muco-purulent or purulent discharge, yellowish or greenish according to the proportion of pus. This is seen characteristically in acute gonorrhea, and commonly results also from chronic endometritis. It is the variety most frequently spoken of as "the whites," when containing but little pus. It stains and stiffens the linen.

(b) Watery discharges may result from simple hyperemia of the genital passages, and are sometimes so abundant as to lead to the suspicion that the fluid is furnished by a hydrosalpinx which periodically empties itself through the uterine orifice of the Fallopian tube. They are also found in cases of cancer, but then the discharge more often assumes the characters of the next variety.

(c) Fetid discharges occur as the result of ulceration, and the principal conditions which produce them are retained pessaries, sloughing fibromyomata and polypi, decomposing products of conception, and, most frequently of all, cancer.

(d) Bloody discharges, other than menstrual, may be due to cancer, endometritis, fibromyomata, polypi, denomatous disease of the cervix, and lacerations. The discharge is often pinkish in cancer, but in any of the above conditions it may vary from a very slight rose tint to the red of almost pure blood.

(e) In the case of a tubal pregnancy which has become interrupted by rupture of the tube, or by the formation of a tubal mole, a characteristic discharge is often present. It is scanty and of a brownish colour, and may continue for many weeks. It is due to disintegration of the decidua which forms in the uterus in cases of extra-uterine pregnancy. A similar discharge may result from the slow disintegration of a polypus or clot within the cavity of the uterus.—(From Sutton and Giles' treatise on the Diseases of Women.)

6. *The causes of pruritus vulvæ*, are:—Irritating discharges; diseases of the vulva; pediculus pubis, round worm and other parasites; reflex irritation from the bladder or genital tract; uterine displacements, rectocele, cystocele, and pelvic congestion; high living, indolent habits, lack of cleanliness; some cases, in which none of the above causes appear to be operative, are said to be of nervous origin.

(To be continued.)

Therapeutic Hints.

Malaria.—L. D. Fricks of the United States Public Health Service, gives the following standard treatment for malaria, which was formulated by the National Malaria Commission, following extensive investigations in Bolivar and Sunflower counties, Mississippi: For the acute attack, 10 grains of quinine sulphate by mouth three times a day for a period of at least three or four days, to be followed by 10 grains every night before retiring for a period of eight weeks. For infected persons not having acute symptoms at the time, only the eight weeks' treatment is required. The proportionate doses for children are: Under 1 year, one-half grain; 1 year, 1 grain; 2 years, 2 grains, 3 and 4 years, 3 grains; 5, 6, and 7 years, 4 grains; 8, 9, and 10 years, 6 grains; 11, 12, 13, and 14 years, 8 grains; 15 years or older, 10 grains.—*Journal of the Am. Med. Association.*

Powdered Charcoal in Chronic Dysentery.—Dr. Fayolle, while medical officer with the troops in the Balkans, treated over 250 cases of chronic dysentery which had proved intractable to the ordinary methods. He found that charcoal powder gave excellent results and allowed patients to absorb rather more solid food than milk without increasing diarrhea, even during the first few days of the treatment. Small doses are not to be given. He started with at least 15 to 30 grams of charcoal powder per day, divided into several doses. The daily dose may be diminished as improvement takes place. The best method of administration is in suspension in tea, coffee, or water. Fayolle suggests that the treatment might be applied in acute cases of dysentery, in all infective diseases with their lesions in the small intestines, and in all ulcerations of the digestive tract.—*Medical Press.*

Gelsemium in Influenza.—William D. D. Small states that at the beginning of the second wave of influenza he and one of his associates carried out investigations with the object of determining the relative value of certain likely remedies. Groups of patients were put upon different drugs, and their progress was noted and compared. Among the drugs tested in this way was gelsemium. The cases treated with this remedy improved in a manner far exceeding those who were given any other drug. All their patients were thereafter put, as a routine, upon moderate doses of gelsemium, in the following prescription:

R

Tr. Gelsemii.....mg xij.

Tr. Belladonnæ.....mg v.

Potass. Citratis.....gr. x.

Syr. Aurantii.....5j

Aq. Chloroformi.....ad 5j

Sig.—One ounce every four hours, for the first twenty-four hours; thereafter half an ounce four-hourly until the temperature is normal.

The remedy should be discontinued after the temperature has reached the normal. In a very small number of cases, the use of the remedy was attended by slight ocular disturbances, and if too long continued it may give rise to mild head symptoms. No other disadvantages were noted in the large series in which it was used.—*Edinburgh Medical Journal.*

THE WORK OF THE AMERICAN SOCIETY FOR THE CONTROL OF CANCER.*

BY CHARLES A. POWERS, M.D.,

DENVER, COLO.

PRESIDENT OF THE SOCIETY.

MY first and very pleasant duty is to thank the officers of this Association for the kind invitation to address you. It is a compliment to the National Society which I represent, and in choosing a title I have felt that the simple one appearing on your program may warrant the iteration of homely truths already well known to you, as well as the setting forth of thoughts which I cherish for the further waging of a vigorous campaign against one of the most dreaded and dreadful scourges which afflict mankind. It is, indeed, with the hope of enlisting the active aid of every member of this important body of surgeons that I venture to lay stress on certain avenues of attack which at this time seem to promise progressive diminution of cancer mortality and suffering.

History of the Society.—Inception of the formation of the Society found place in the American Gynecological Association, delegates from which met in May, 1913, with delegates from the American Surgical Association and other representative national bodies, to found a national organization, "to disseminate knowledge concerning the symptoms, diagnosis, treatment, and prevention of cancer, to investigate the conditions under which cancer is found, and to compile statistics in regard thereto."

In establishing an organization with this purpose, the founders gave practical expression to their hope and belief that a nation-wide campaign of public education regarding cancer would save thousands of lives now needlessly sacrificed every year because of ignorance of the warning signs of this insidious disease and delay in seeking competent medical advice and treatment even after the symptoms are recognized.

In the latter part of 1913 and in 1914 a certain amount of preliminary work was done, especially in Massachusetts.† Literature (to which later reference will be made) was carefully prepared for both the profession and the laity. Then came the Great War, with its attendant responsibilities, anxieties, and duties, and the work of the Society

*Read by invitation at the Annual Meeting of the Southern Surgical Association, Hot Springs, Va., December 14, 1920.

†Thanks to the sustained interest of Dr. Edward Reynolds.

naturally languished. During the past year, however, state and local organization has been effected, and, to paraphrase a war phrase, "the decks have been cleared and the Society is ready to go into action."

Immediate Aims of the Society.—Greenough (*New York Medical Journal*, Oct. 16, 1920), in an illuminating address read before the Medical Society of the County of New York, says that in the cancer problem four lines of attack present themselves for consideration:

1. The education of the public to the early symptoms of the disease.

2. The instruction of the medical profession as to the actual facts of this serious situation, to bring about earlier diagnosis.

3. The promotion of investigations on the part of surgeons in regard to more effective means of operative treatment.

4. The promotion of investigations in the laboratory in regard to the causes of cancer, and of methods of treatment other than by operation.

I take it that at this time the Cancer Society may well occupy itself with the first two of these contentions; to effect the widest possible diffusion of knowledge among the laity regarding the early symptoms of cancer, and at the same time to aid in bringing the members of our profession to a clearer and higher conception of their own duties and responsibilities. The two endeavors go hand in hand. We know that at this time an average period of ten months elapses between the discovery by the given man or woman of the first symptoms of cancer and the seeking of medical advice. It is our aim to reduce this period as nearly as possible to one day. Further, we are to endeavor to aid the given practitioner in acquiring the ability to make a thorough, suitable examination and to give adequate advice.

There is not one of us who fails to understand the natural desire for concealment on the part of a given patient. Only too often is cancer considered a disgrace. It is in no way a disgrace; it is only one of the most terrible of misfortunes. There seems to be no suitable substitute word for the word "cancer." I feel that one of our important duties consists in familiarizing the people with this word, in teaching them that the condition is not a blood disease, that it is not contagious, that it cannot be communicated by one person to another. It is certain that constant effort toward familiarization with the word itself will slowly and steadily tend to rob the word of a part, at any rate, of its terrors. It is already found that in communities where a considerable number of suit-

able talks* have been carefully made, people tend more and more toward open discussion of the condition. The whole subject should be brought out into the light.

Organization.—The American Society for the Control of Cancer maintains a central office at No. 25 West Forty-fifth Street, in the City of New York, this office being under the care of a lay executive secretary,† he being a trained public health worker. During the past year a thorough regional and State organization has been effected, and it may not be amiss to give a table of this. In certain areas regional directors have been appointed, each director looking after a given group of States, appointing State chairmen, subcommittees, and the like, and effecting a general organization of the work. Thus, the New England States, with the exception of Connecticut, are under the care of Dr. Robert B. Greenough of Boston. Dr. J. C. Bloodgood of Baltimore looks after Maryland, Virginia, and Delaware; Dr. Fred T. Murphy of Detroit takes charge of Michigan, Ohio, Wisconsin and Illinois; Dr. C. Jeff Miller of New Orleans looks after Louisiana, Mississippi and Alabama; Dr. Donald C. Balfour, temporarily a resident of Denver, takes Colorado, Arizona, New Mexico, Utah, Wyoming and Western Kansas; Dr. F. J. Taussig of St. Louis, Missouri, Oklahoma, Arkansas, and eastern Kansas; Dr. Verne C. Hunt of Rochester, Minn., has Minnesota, Iowa, North and South Dakota, and Montana; Dr. H. M. Sherman of San Francisco takes California and Nevada, while Dr. E. F. Tucker of Portland, Ore., has charge of Oregon, Washington, and Idaho.

State chairmen are as follows: Massachusetts, Dr. Edward Reynolds of Boston; Connecticut, Dr. Joseph M. Flint of New Haven; West Virginia, Dr. F. L. Hupp of Wheeling; North Carolina, Dr. J. W. Long of Greensboro; South Carolina, Dr. R. S. Cathcart of Charleston; Georgia, Dr. G. R. White of Savannah; Florida, Dr. Ralph N. Greene of Jacksonville; Kentucky, Dr. I. Lindenberger of Louisville; Tennessee, Dr. W. D. Haggard of Nashville; Indiana, Dr. Miles F. Porter of Fort Wayne; District of Columbia, Dr. James F. Mitchell of Washington; Nebraska, Dr. Palmer Findley of Omaha; Texas, Dr. A. C. Scott of Temple; New Mexico, Dr. James A. Rolls of Santa Fé; Washington, Dr. C. W. Sharples of Seattle; Idaho, Dr. L. P. McCalla of Boise; Wisconsin, Dr. John L. Yates of Milwaukee; Illinois, Dr. Carl B. Davis of Chicago; Ohio, Dr. J. Ranshoff of Cincinnati; Michigan, Dr. Reuben Peterson of Ann Arbor; Arkansas, Dr. Dewell Gann of Little Rock; Colorado, Dr. F. W. Kenney of Denver; Utah, Dr. R. Richards of Salt Lake City. Hawaii is in charge of Dr. James R. Judd of Honolulu. That the Society is fortunate in having the active aid and support of these men‡ goes without saying. Their names furnish ample guaranty that the work is being done carefully, conservatively, thoroughly and efficiently.

*In Colorado, where a goodly number of these talks have been given, an increasing desire to hear them is manifest.

†Mr. Frank J. Osborne.

‡On the Executive Committee, which meets monthly in New York, under the chairmanship of Dr. Howard C. Taylor, are men of the type of Cleveland, Lienthal, F. C. Wood, Ewing, F. K. Hoffman.

The Relation of the Cancer Society to the Medical Profession.—Under the competent chairmanship of Dr. Greenough of Boston a committee of the Society has prepared a handbook for the profession, and it is our endeavor to have this distributed as widely as possible. This distribution can be effected through the agency of State Medical Societies, State Boards of Health, etc. Having had but little share in the preparation of the various forms of the literature which our Society puts forth, I can, perhaps, gracefully speak of the conservative excellence of these publications. Certainly, I do not believe that any of our experienced surgeons can fail to derive pleasure and profit from reading this little professional brochure, as well as from the lay pamphlets.

Sessions of our State and county medical societies, special national societies, the various sections of the American Medical Association, etc., may well be devoted with increasing frequency to this most important subject. At all of these meetings the importance of suitable lay education may with propriety be emphasized, and we must aid in arranging cancer meetings for the dental societies. The dentist is not infrequently the first to observe the appearance of mouth cancer; he is naturally anxious to know the early symptoms.

The Instruction of Nurses.—This is important. The Cancer Society has prepared a special pamphlet for nurses; this should receive the widest possible distribution. Special talks on the early recognition of cancer should be made before the various associations of graduate nurses, as well as before the nurses who are taking their hospital training.

The Education of the Laity.—Certainly, no activity in the domain of cancer can be more important than this, and I am convinced that the most valuable way of instructing the people in the simple facts connected with cancer lies in the giving of well considered talks to groups* of varying size. In these talks assurance of plain leading facts can be given. The audience may be told that cancer is not hereditary, that it is not contagious, that it is not a blood disease, that it is at first local. The statement can truthfully be made that in very many regions it is curable when taken early. Simple, plain, non-technical description may

*In Denver, during the last year, many cancer talks have been made before such bodies as: The Woman's Club, Department Store Employees, the Knights of Columbus, the Elks, the Colorado Educational Association, the Association of State Librarians, the State Congress of Social Workers, Women's Aid Societies of various churches (Protestant, Roman Catholic and Jewish), the Y. M. C. A. and the Y. W. C. A., the Association of Collegiate Alumnae, the Protestant Ministers' Alliance, the Junior League, the Employees of the Telephone Company and of the Tramway Company, the Garment Workers' Union, the Parent Teachers' Associations, etc. In addition, articles have been read before the Colorado State Medical Society and the Denver County Medical Society.

Colorado Springs, Col., is a town of 25,000 people. It is both interesting and gratifying to note that during the month of October, 1920, Dr. Charles F. Gardiner, the chairman of our Cancer Committee there, made, with the assistance of members of his committee, no less than thirty cancer talks to lay groups of varying size, largely groups of women. Such a task is accomplished in a personal way; one can but wish that in every town similar work might be done.

be given of the early symptoms in such regions as the breast, the uterus, the skin in its various portions, the lip, etc. These are very simple matters to us, but it is astonishing how ignorant the lay people are of the plain facts which they should know. Speakers universally report an earnest desire on the part of their hearers to learn these facts; approaching a group of people in a spirit of broad human sympathy, it is pathetic to note the eagerness with which they listen.

The Society has very carefully prepared pamphlets for distribution at these lay meetings, and it also has illustrative lantern slides which materially aid in pointing the moral and adorning the tale. It is our experience that these talks should be brief. A well equipped speaker can say a great deal in fifteen* minutes. A few leading points can be made with clarity, and the little pamphlets which the auditors take home with them will serve to recall these facts and emphasize them. We all know that women are much more interested listeners than are men when it comes to the consideration of this particular subject.

Visiting and public health nurses can distribute our pamphlets, and by simple instruction spread the gospel. We endeavor to have a succession of suitably written articles in such lay periodicals as the *Outlook*, *Independent*, *Woman's Home Journal*, *Saturday Evening Post*, etc.

Publicity.—This is the keynote to our campaign; it is the crux of our problem. One need say but little regarding the instruction of the members of our profession; our Society simply desires to aid in every possible way by the distribution of helpful handbooks, by urging† suitable meetings which are wholly or in part devoted to this subject, meetings of national, State, or local medical societies. At these medical meetings emphasis may properly be laid on the great importance of constant instruction§ given the laity.

As we approach the instruction of the laity we find many avenues¶ open to us. Carefully given talks to groups of men, or women, or of both, as has been outlined. Distribution of the Society's pamphlets at these meetings. Notice given of these meetings in every possible way, including the daily press.

*A 12 or 15 minute talk can often be interpolated in the course of the regular program of the annual meeting of such societies as: The Federation of Women's Clubs, State Federation of School Teachers, Social Welfare Organizations, State Association of Librarians, etc.

†The question is often asked whether such a campaign as is outlined here does not tend to create undue fear; "phobia" so to speak, in the minds of the people who hear the lectures and read the articles. I am certain that no harm is done in this way. It is better that a few people should be unduly disturbed than that a single case of beginning cancer should be neglected. Our intelligent medical profession can easily set people aright.

‡The aid of all existing agencies is earnestly asked. Medical societies, State and local Boards of Health, the Red Cross, and similar organizations can constantly help. It is gratifying to note that the American College of Surgeons is laying stress on cancer education in its meetings held in various parts of the country.

§Dr. T. W. Huntington of San Francisco is giving splendid aid in the matter of articles sent medical journals, the lay press, etc.

¶Cancer "days" and "weeks" have been successfully held by Dr. Wainwright of Scranton, Pa., and by others.

In this matter of notices, reading articles and the like in the daily press, I hope that you will bear with me when I say that I believe that we, as a profession, have, in large part, leaned backward in our effort to avoid publicity. Our aim is to get our message (let us call this a "Message of Hope," if you will) before the people, and this must be done in a very authoritative way. At times the name of the American Society for the Control of Cancer, or of a given State or county medical society or other organization, may suffice. More often does the public desire to know the name or names of one or more well known physicians or surgeons who make themselves responsible for what is said. We all know, we all respect, the splendid ethics of our profession, and I think that we support these ethics when we, in a suitable way, lay aside our personal prejudices and desires.* I grant you that it is easier to be a philosopher at the age of retirement from practice than it was at twenty-odd years or thirty-odd or even at the steady age of forty-odd. Further, one's point of view may be changed very materially after he has retired from active practice. And yet, in this so very important matter, I know that you will feel with me that our duty to humanity is paramount.

The universally distributed motion picture houses of to-day are capable of furnishing wonderfully effective publicity. In preparing for a recent cancer campaign in Denver we were fortunate in being able to have the following notice set forth during periods of from two to seven days in eight of the principal downtown motion picture theaters:

Cancer.—The American Society for the Control of Cancer says:

1. That 85,000 people die yearly in the United States from this dread disease.

2. That the majority of these deaths could be avoided if the condition were taken early.

3. That in early recognition lies the hope of cure.

Cancer campaign in Denver next week! Watch the newspapers for notices!

It was conservatively estimated that the foregoing notice was seen by at least 100,000 people. The effectiveness of such publicity is apparent.

The Cancer Society has at this time in preparation two instructive motion picture plays, one for the profession and one for the laity. It is expected that these will be produced in the immediate future.

In further connection with this matter of publicity I would like to say to you that one of the most distinguished members of this Association, a surgeon who has long been a pioneer in the war against cancer, Dr. Joseph C. Bloodgood, has for some years inclosed with letters, etc., to former patients and their physicians, a carefully worded circular letter of cancer information. This is certainly one of the best possible ways of carrying on our campaign; one can but think of the wonderful good which would be done if every physician and surgeon should adopt this plan. In a recent letter Dr. Bloodgood says: "I think I have the evidence to show that I have done more good by teaching the public and the medical and nursing profession than I have done by any other means."

*I know that I shall be understood in this. I mean that we should not withhold clear, direct statements which are made solely for the public good.

ing professions than even by the operative treatment of cancer." Would that each one of us were able to say this!

Mention has been made of carefully prepared articles published in the more important lay papers and magazines.

I have already trespassed on your patience and will refer but briefly to such matters as the quick advertisements in newspapers, magazines, etc., which our Society, through its officers and committees, is endeavoring to have abolished; to the important matter of the employment of radium and the x-rays in the treatment of cancer, which our Society looks upon with deep, conservative interest; to the splendid research work which is going on in such responsible institutions as the Crocker Institute for Cancer Research of Columbia University, the Harvard Commission for Cancer Investigation (Huntington Foundation), the General Memorial Hospital of New York, the Skin and Cancer Hospital of St. Louis, the New York State Laboratory of Malignant Disease at Buffalo, and the other splendid foundations both here and abroad. In the fullness of time a specific for the prevention or cure of this terrible disease will be found. Even then, however, education will have its place, and in the meantime education holds a first place. And it is in this thought that I confidently ask each of you, in his given community, to become an active educational agent.

THE UNIVERSITY CLUB.

CHRONIC APPENDICITIS, SO-CALLED.

By F. GREGORY CONNELL, M.D., F.A.C.S.,

OSHKOSH, WIS.

WITH the object of attempting to correlate the symptomatology and the pathology, it has been customary for a number of years to subdivide cases of appendectomy into the following: (a) Those in which there is a pathologic appendix, unquestionable and demonstrable to the naked eye; (b) those in which the pathology in the appendix is questionable or not demonstrable to the naked eye.

A study of the previous and after history, with the remote result in these two classes of cases, has led to quite constant and rather instructive findings:

(a) With demonstrable unquestionable pathology:

1. The history usually gives definite previous acute attacks.
2. Symptoms between attacks are absent or slight.
3. Results are satisfactory—that is, symptoms return in only a small percentage of cases.

(b) With questionable or absent pathology:

1. The history rarely gives a definite previous acute attack.
2. Symptoms are more or less constant.
3. Results are unsatisfactory—that is, symptoms return in a large percentage of cases.

This report concerns chiefly the so-called "chronic appendix," but a brief preliminary review of the acute cases may be found of interest, as a contrast.

In the history of acute appendicitis, one finds, as a rule, the story of definite, more or less typical attacks, with absence of localized pain or tenderness

in the region of the appendix, between the attacks, which is in marked contrast with the history of the usual so-called chronic appendicitis.

In the acute case with evident pathology a satisfactory result is to be expected in a very large percentage. In the small percentage, the unsatisfactory results in these cases are rarely, if ever, due to a return of the original symptoms, differing strikingly from the chronic case with unsatisfactory result, but are due to such causes as coincident or complicating disease, hernia, fistula, incomplete operations, ileus (acute not chronic) due to adhesions. Without evident pathology it is obvious that a mistaken diagnosis has been made and that unsatisfactory results are to be anticipated.

In the acute cases this classification according to the evident pathology is satisfactory, but in chronic cases it is exceedingly difficult to accurately gauge the extent of the disease by the gross pathology, and in many cases it is absolutely impossible to differentiate between pathological appearance due to post-inflammatory conditions and that due to developmental imperfections, or other non-inflammatory conditions.

An appendix in which there has been a previous acute process, even gangrenous and suppurating, with abscess formation, except for the presence of easily overlooked scars, may appear comparatively normal at later appearance; while an appendix removed during the course of an operation for other conditions, performed in a purely prophylactic manner, with an absence of symptoms suggestive of appendicitis, may show signs that might be considered pathologic, such as deformity, thickening, congestion, enteroliths, or "adhesions." As examples, one might mention the report of Williams and Slater¹ of the Boston City Hospital on the condition of the appendix in 500 laparotomies in patients representing no symptoms of appendicitis, 167, or almost exactly one-third, of whom showed changes in the appendix. Pitzman² claims that there is "no surgical appendicitis without organic stricture. Beutner³ objects to systematic appendectomy as a routine supplement to operations on the adnexa. Microscopic examination of the appendix in 87 cases in which this had been done showed that the appendectomy had been actually indicated in only four of the cases. C. Waegeli⁴ studied 896 laparotomies, 16.4 per cent. of which showed lesions of the appendix. After careful study of this material he does not believe simple hyperemia, swelling of the appendix, superficial adhesions to the diseased adnexa furnish sufficient indication for ablation. A recent important contribution reporting the results after operation in cases of chronic appendicitis is by Chas. L. Gibson,⁵ who emphasizes the necessity of follow up reports of remote results in cases of this type. J. B. Deaver⁶ discusses chronic appendicitis, but emphasizes those resulting favorably. The case that should be given close study and attention is the case of operation for chronic appendicitis in which the same symptoms present after appendectomy.

The gross section and even the histological picture may be very difficult to interpret, the evidence of a previous inflammation, unless progressed to destruction, may be obliterated, and if destructive it may be overlooked unless serial sections of the entire organ are made; the same microscopic section

may be variously interpreted by different pathologists, the personal equation of the one looking through the microscope being of great import in such a differentiation.

The pathology of appendicitis has been very ably presented, by Kelly, Aschoff and others, but in an article by Moschcowitz one finds considerable attention given to the chronic type of disease.

Eli Moschcowitz' in an admirable study of the pathological diagnosis of diseases of the appendix based on the study of 1500 specimens, emphasizes many important points. Referring to chronic appendicitis he says:

The histological characters of a healed or chronic appendicitis are therefore the following:

1. A narrow lumen (stricture) or
2. Complete obliteration of the lumen by new connective tissue.
3. The absence of mucosal crypts. This absence indicates, except in cases where the lumen of the appendix has been dilated from other causes (to be shown later) that a previous acute suppurative inflammation has taken place. This phenomenon is important in differential diagnosis, in cases where there is a question as to whether the lumen of the appendix is narrower than normal.
4. The widening of the submucous connective tissue zone.
5. The attenuation and diminution (or even complete disappearance) of the lymphoid tissue.
6. The infiltration of the muscular coats by new connective tissue, and consequent deformity.
7. The thickening, increased density and deformity of the peritoneal coat.

I may say, in passing, that I have closely studied Moschcowitz's photomicrographs in conjunction with text, and with these in mind have studied sections of over one hundred consecutive appendices removed for acute and chronic appendicitis, and during the course of operations for other purposes.

The acute may always be recognized, but in attempting to differentiate between those removed for symptoms and those without symptoms, my results were not more accurate than those one might expect by the rules of chance.

Appendicitis has been subdivided and classified into many more or less definite groups, for example:

Barker, groups acute appendicitis into four types as follows: 1. Acute simple catarrhal appendicitis. 2. Acute, diffuse, non-suppurative appendicitis. 3. Acute suppurative appendicitis with abscess formation. 4. Acute fulminating appendicitis, gangrene of the appendix and perforative appendicitis.

Da Costa' well says: "As a matter of fact, genuine appendicitis, that is, actual inflammation of the appendix, is always one disease which varies in intensity and complication. It is useless to divide it into a great number of symptomatic groups."

Robert T. Morris' presents a characteristic paper entitled "Notes on Four Kinds of Appendicitis," and gives a very satisfactory discussion of the symptoms of the so-called chronic appendicitis under the heading "Irritative Appendicitis," which would be most convincing were it not for the fact that in many cases the symptoms persist or return after a successful appendectomy. Another type of chronic appendicitis Morris calls "Syncongestive Appendicitis," which occurs as a common complication of general enteroptosis. The explanation for the appendix presenting symptoms of its own pecu-

liar sort is again most rational and satisfactory, but need not be repeated here for the reason that this same localization of the pain occurs frequently after the removal of the appendix. Morris's article concludes with the following paragraph: "Syncongestive appendicitis does not often call for operation. The symptoms of local pain and tenderness disappear when the swelling of the cecum disappears or when tolerance toward chronic swelling of the appendix has become established."

This attempted subdivision of appendicitis into cases requiring and cases not requiring operation calls for considerable presumption on the part of the surgeon, is a backward step, and will lead to trouble, dissatisfaction, and an occasional disaster. Many years of teaching, with much sad experience, have finally driven home the truth that appendicitis is a surgical disease and that one does but little better than guess in an attempt to foretell the outcome as to whether there will be a natural subsidence of symptoms and spontaneous recovery, or suppuration, gangrene, abscess or peritonitis.

With our present knowledge, the diagnosis of appendicitis calls for the advice to remove the appendix, not because all such cases lead to peritonitis, but because one may not tell, with any degree of accuracy, which will and which will not lead to serious complication.

By calling a condition appendicitis that is not appendicitis (judging from similar cases proved to be unrelated to the appendix), even modifying it by some adjective, merely makes the subject more complicated and causes confusion. Such confusion relative to the question of *chronic* appendicitis may be seen in the following report from the Mayo Clinic by Graham and Guthrie":

Chronic appendicitis with fecaliths	58
Chronic adherent appendices	20
Chronic appendicitis	14
Chronic obliterating appendices	8
Chronic appendicitis, cystic tip	6
Subacute appendicitis	6
Carcinoma of appendix	1
Tuberculosis of appendix	1
Acute appendicitis	1
Total	115

As showing the trend of opinion, I take pleasure in referring to the preface of the last edition of "Physical Diagnosis" by R. C. Cabot," in which we find an expression of growing skepticism as to the diagnosis of chronic appendicitis.

There is thus plainly indicated the necessity of a definition of chronic appendicitis before one may discuss it intelligently.

Definitions from many text books or articles could be quoted, but they are all quite similar and equally unsatisfactory.

Barker' very rationally subdivided *chronic* appendicitis as follows: (1) That following an acute process; (2) that in which the process is chronic from the start. He discusses the second subdivision of the question in the following manner:

In chronic appendicitis the patients suffer from discomfort in the right iliac fossa. Slight tenderness can be elicited on pressure. There is usually obstinate constipation and often hyperchlorhydria, though a normal acidity, or even a subacidity of the stomach-juice may be met with. In the obliterative appendicitis, or in-

volutional appendix, there may be no symptoms, the condition being found accidentally at operation done for other causes, but in the so-called "harmful involution of the appendix" the symptoms include headache, anorexia, chronic intestinal dyspepsia, discomfort in the region of the appendix, and tenderness at Morris's point. Sometimes a narrow hard appendix can be palpated.

This leaves very much more to be said regarding a subject so important that it might be called the most frequently treated (surgically) disease of the abdomen.

The above definition will hardly answer because in cases of recurrent appendicitis, definite, unquestionable and corroborated by competent testimony, or those in which operation finally proves the diagnosis, such symptoms as above detailed are not the rule between attacks; and more important still, such symptoms many times persist after successful appendectomy.

Inasmuch as it is difficult to gage the extent of the pathology in chronic appendicitis from the symptoms, *before* the abdomen is open, as it is still difficult from the gross pathology *after* the abdomen is opened and the organ is palpated and inspected; and as it is still difficult from the histopathology after the appendix has been removed and subjected to microscopic study, one may anticipate a certain degree of complexity and difficulty in a study of the subject of chronic appendicitis. A condition that is among the most difficult to diagnose within the entire list of surgical diagnoses, but one which is made everywhere, every day, by everybody, with as much nonchalance and much less evidence than is called to one's support in commenting upon the weather. One might say of this condition that it is the most treated and the least diagnosed surgical disease. In the authoritative text books and treatises upon the subject of appendicitis one finds hundreds of pages devoted to *acute appendicitis*, with often less than a proportionate number of lines, at most paragraphs, devoted to the subject of *chronic appendicitis*, while in every hospital in the United States hundreds of chronic appendicitis cases are being operated upon to the one acute case.

Because of the occasional error in differentiating between normal appendix and chronic inflammation of appendix by the signs and symptoms and even by the gross and microscopic picture, it has been suggested that a study of the "previous history" be called upon as an aid in such a differentiation. The previous history is difficult to obtain and still more difficult to correctly interpret. To properly correlate the more or less vague, indistinct and often incorrect recital of an attack of abdominal complaint, given often years after its experience, is many times utterly impossible, and the previous attack may have been anything from renal colic to dysmenorrhea. The patient's idea as to the severity of the attack is of little value, of course, when we remember that cases under our own observation may continue at work with an acute appendicitis, which is proved by finally terminating in abscess formation. In securing the history I have been astonished to find the number of times in which the patient states that the attending physician did not even take the temperature in the attack under consideration, and in which the patient walked to the office for

examination, complaining of pain in the right side, frequently calling the complaint appendicitis, and in which the examination consisted of merely palpation of the right iliac fossa. In reply to my question, many times I have been told that the *left* iliac fossa was not examined or inquired about. After such a superficial examination, which is worse than none, the advice, "to be operated upon tomorrow morning," was given and, to the detriment of medicine and surgery, has many times been acted upon.

One can but regret the lack of some authority regarding the question of operations for chronic conditions, similar to that in military service and the draft activities, by means of which errors were reduced to a minimum. It would seem that in matters as important as life and health, the exercise of such authority might well be extended to a peace footing. For example:

A soldier home on a furlough complained of pain in his abdomen, consulted a physician, who made a diagnosis of appendicitis and advised operation. His commanding officer was notified and the following laconic reply was received that is well worth repeating, and operating surgeons might well learn it by heart, to many times ask themselves in the absence of some other authority: "Telegram concerning E. M. received. If appendicitis is acute, may operate. Complete clinical history with diagnosis and method of arriving at diagnosis required and must satisfy local military surgeon. Answer what action you are taking."

Suffice it to state that the man was referred to the Medical Advisory Board, which, in time, reported a diagnosis of "hysteria"—which time has since proved to be correct.

We have made an effort to subdivide supposed cases of chronic appendicitis into those in which there is and there is not given a history of a previous acute attack that might reasonably be supposed to be appendicitis. We would arbitrarily suggest that an acute attack be considered probably only in cases in which there was pain, tenderness, temperature, nausea or vomiting, with invalidism necessitating rest in bed for at least one day. This is recognized, of course, as not being positive, but it gives one a suggestion as to the nature of the so-called "acute attack." This led to the rather consistent findings that:

A. Chronic appendicitis with known previous acute attack: the symptoms in the interval were slight; B. Chronic appendicitis with no known previous acute attack: the symptoms were more or less constant.

It led to the further constant finding relative to the remote result following appendectomy, the result not being considered until the elapse of one year or more:

Chronic *with* evident history of acute attack: *Cure* following appendectomy: large percentage. *Not cure*: small percentage.

Chronic *without* evident history of acute attack: *Cure*: Small percentage. *Not cure*: large percentage.

In a consideration of chronic appendicitis Class A, in which operation is usually followed by cure, need not concern us except as to show us the dif-

ference between A and B. Class B concerns us because it is one in which our result is not satisfactory because of either improper method of treatment (which is not reasonable if our diagnosis is correct) or an incorrect diagnosis, and consequently a wrong and ineffectual line of treatment.

If this conclusion is correct, and it would seem to be so, then it is incumbent upon us to find out what is the cause of the right iliac pain. What is there in the right iliac fossa and not in the left that might give rise to such symptoms as are presented in the complaint commonly misnamed "chronic appendicitis"?

In the first place, as to this pain being in the right iliac fossa and not elsewhere: In many cases of this type I find, on careful examination, that there is objective pain and tenderness in both the right and the left iliac fossa, as well as in the epigastrium and hypochondria, if carefully searched for, while the subjective pain is more often complained of only in the right side. Therefore it may be said that in a certain proportion of cases the pain and tenderness is only in the right side for the simple reason that it is looked for only in the right side.

Royster" has called attention to left-sided pain in women, in relation to adhesion between the tube or broad ligament and the sigmoid, and recommends a plastic operation upon such adhesions, which operation I have carried out many times with results that leave me unconvinced as to its value.

Of the cases in which the pain and tenderness are in the right iliac fossa, we know it is *not* due to certain conditions, for example: (1) The appendix. (2) Pericolic membrane, ileal kink, similar definite bands. (3) "Adhesions." (4) Coincident pathology.

Not due to the appendix because of previous appendectomy: This is the one outstanding fact regarding this subject. Relief of symptoms may follow the removal of appendix and there may still be a rational opinion that recovery took place in spite of the operation. But in cases operated by removal of the appendix followed by a return of the same symptoms, we are correct in saying that the symptoms were not due to the appendix.

In 1914 the author, under the title "The Chronic Abdomen," considered at length a series of cases of secondary operation for persistent symptoms following appendectomy. Again in 1916 the writer once more called attention to this type of abdominal complaint and presented a detailed analysis of 87 such cases in an article entitled "Pseudo Appendicitis."

Not due to definitely named bands or membranes such as Lane kink; ileo pelvic band; genito-mesenteric fold of Douglas Reid; Jackson's membrane; parieto-colic fold of Jonnesco and Juvara; the bloodless fold of Treves; and others. In 1911 the writer called attention to these bands, membranes and kinks under the title of "Ileo-cecal Adhesions—Lane's Kink and Jackson's Membrane." This was followed in 1912 by a contribution entitled "Etiology of Lane's Kink, Jackson's Membrane and Cecum Mobile," in which an attempt was made to show that these bands and membranes were not of inflammatory origin, and in "A Review of Nineteen Cases of Pericolitis and Ileal Kink in Which the Ap-

pendix had Been Previously Removed," that they were not the cause of the symptoms that led to appendectomy, such conclusions are now quite generally accepted. (See the authoritative work of Samuel Clark Harvey" entitled "Congenital Variation in the Peritoneal Relations of the Ascending Colon, Cecum, Appendix, and Terminal Ileum.")

Not due to adhesions.—In this day of promiscuous operations and operators a most unusual opportunity has been given to perform definite experiments within the living human abdominal cavity which, if recognized, would have served a splendid opening for the antivivisectionists who have been so strenuous in their efforts to eliminate experimentation upon the lower animals that they have overlooked this field of activity, which might much better have been the object of their misdirected efforts. All that has been necessary to carry on a series of such experiments was to observe, tabulate and report the findings before, during and after the various multiple abdominal operations that have been so common in the past few years—an opportunity so commonplace that it has been many times overlooked and neglected, a failure to embrace an opportunity that I fear will be a long time returning.

The glib manner in which the laity and many of the profession make a diagnosis of "chronic appendicitis" has given a rather unusual opportunity for observation and study of the abdominal findings and of the results following treatment.

The first defense in failure to relieve symptoms after an appendectomy for chronic appendicitis, has been an explanation attributing the persistence of symptoms to "adhesions." Very little seems to be really known about adhesions, their cause and prevention, despite the many communications upon the subject. One fact has been constantly evident in my observations at secondary abdominal operations following appendectomy, viz., that in practically every case, examination of the site of the appendiceal stump reveals the absence of adhesions. Adhesions to the abdominal scar were frequent; but the visceral scar, despite the necessary traumatism and manipulation, was non adherent. The exact significance of this has not been presented satisfactorily, though Quain has emphasized the importance of injury to the intercostal nerves in the development of abdominal adhesions. In these cases of supposed adhesions an acute obstruction is a most uncommon occurrence. In cases of true obstruction coming to operation, the previous history is most unlike that given in these cases of supposed adhesions. After definite attacks of acute appendicitis the adhesions that usually cause symptoms are those that produce ileus.

Another important point that is often overlooked is that these same symptoms supposed to be due to *post operative* adhesions were present *before* the operation which was supposed to cause the adhesions.

Repeated operations in which adhesions were divided at secondary operation have failed to permanently improve the symptoms. And repeated secondary operations for various conditions in which there had been no return of the original symptoms have many times shown the same adhesions that are here innocuous.

Thanks to these many operations for various causes there is a failure to accept "adhesions" as a cause of symptoms of "chronic appendicitis" after the removal of the appendix.

Not due to pathology in the stomach, duodenum, gall bladder, liver, kidney, ureter or bladder, tubes, ovary or uterus, vertebra, sacro iliac articulation, or diseases of the nervous system. That these symptoms are not due to the usual or unusual abdominal disease named is granted for argument's sake; of course, there is always a possibility of overlooked abdominal organic pathology, but a weakness on the part of the laity and, in turn, of operators, to attribute abdominal symptoms following unsatisfactory primary laparotomies to "adhesions" has again made a most unusual opportunity to allow re-examination of these cases during which coincident diseases have been excluded.

Multiple operations have sometimes located the cause of the symptoms in some other intraabdominal or related organ or structure, but in the class under consideration, by no means a negligible class, subsequent general exploration, often repeated many times, has proved other usual sources to be negative, or such sources have been reasonably excluded by careful study.

So that leaves for our consideration cases of "chronic appendicitis" in which the appendix is not the cause of the trouble, neither are "adhesions," and, to the best of our knowledge, neither are the other possible sources of pain in this region, such as the above enumerated list of diseases.

The explanation of nervousness, neurasthenia, psychasthenia, etc., seem to do no explaining in these cases. They are nervous, of course, but this does not explain the reason for pain on the right side and not on the left. One neurological consultant, in all seriousness, suggested that the reason for the localization of pain, spasm and tenderness in the right side was that these people *knew* that the appendix and gall bladder were on the right side, and therefore their choice of a location for their pain and hypersensitiveness!

If the above remarks will emphasize the fact that certain cases of so-called chronic appendicitis may not be remedied by appendectomy, they will have fulfilled their purpose. The cause of the symptoms in such cases, it would seem, must lie more central than in the appendix itself, either in the cecal or colonic mucosa or wall, the ileocecal valve, the root of the mesentery, or still more central in the vagus or sympathetic nerve supply, or in the ductless glands.

A CONCEPT OF X-RAY PATHOLOGY.

V. OSTEOPATHY.

By A. J. PACINI, M.D.,

WASHINGTON, D. C.

CHIEF OF LABORATORY AND X-RAY SECTION, HOSPITAL DIVISION,
U. S. PUBLIC HEALTH SERVICE.

IN the study of the x-ray pathology of bone, there are six structures that interest the roentgenologist. These are: (1) Bone tissue, (2) Marrow, (3) Periosteum, (4) Cartilage, (5) Synovia, (6) Ligament.

BONE.—Bone is composed of calcium salts and of organic material. It is the same wherever it is found, differing only in the arrangement and in the relative proportion of inorganic to organic constituents. Two general classes of bone are recognized; the dense and compact, and the soft spongy or cancellous. In each class the bone is the same. Dense bone occurs at the circumference of the shafts of the long bone, and generally as a layer on the outside also of spongy bones. Parallel to the long axis of the bone a system of channels, the Haversian canals, are directed. The shaft of the bone is not to be regarded as an external layer of dense bone filled with a cylinder of marrow, but as a mass of bone differing in the relative amount of bone and marrow as the center is approached; that is, at the circumference of the bone there is relatively little marrow, while in the middle of the bone there is relatively little matrix.

MARROW.—Normally, marrow may be red or lymphoid, or yellow and fatty. Red marrow is typical. It carries various cells, the derivation, function, and destination of which are still only partially known. Marrow is not a passive filling for the bones but is one of their active constituents busily engaged in building up and tearing down osseous tissue. It is important to remember that the changes incident to disease begin first in the marrow; so that bone may be considered as consisting essentially of two parts: (1) Non-vital matrix, (2) Vital cellular content.

The first of these parts is anatomical, the other physiological. The structural arrangement of bone is such that the vital protoplasmic element with its blood vessels is inclosed within the walls of a rigid non-vital framework of mineral salts. The vital element, inclosed in the bone, is possessed of the property either gradually to absorb the rigid structure that incloses it, or to increase the extent of rigid structure by depositing thereon additional mineral salts. Bone is radiopaque, marrow is radioparent.

PERIOSTEUM.—The periosteum is composed of

two layers; an inner or cellular and an outer or fibrous. The inner is thick in children and thin in adults. It bares a strong analogy to the marrow of the subadjacent bone. It has similar functions to the marrow and is vulnerable to the same diseases. It is proper to regard it as a layer of marrow on the outside of the bone not at all separate or distinct from the marrow in the interstices. The two communicate by small channels or canals in the bone and contribute to nourish the bone tissue.

The outer layer of periosteum is relatively functionless and appears to serve as a mechanical cloak to protect the bone from crass injury. Where joint cartilage begins, at the ends of the long bones, the outer fibrous layer of the periosteum is continuous with the ligament; and for the purposes of x-ray pathology the inner or cellular layer may be regarded as continuous with the synovia.

THE JOINT.—A joint is a closed cavity between two bones in which two tissues abound. These are the cartilage and the capsules; where one begins, the other ends.

Cartilage is embryonic bone in potentiality. It is connective tissue, fundamentally fibrous in structure. Normal cartilage is radiopaque, or at most radiolucent; but if the nutrition of the cartilage is disturbed, or if the joint be put at rest, the real fibrous structure of the cartilage becomes evident, the striæ attaining a radiolucency and sometimes radiopacity sufficient to render them identifiable on the x-ray plate. Deep in the cartilage these fibers are at right angles to the surface, more superficially, they are parallel to the surface. Joint cartilage forms an absolute barrier against the extension of disease from the bone into the joint until the cartilage has been perforated by cutting off its nutrition. This is an important physiological fact. It is a positive sign, in x-ray pathology, in the differentiation of malignancy and nonmalignancy. A malignant growth cannot traverse a joint. Any x-ray lesion of a bone that crosses a joint is, *a priori*, not malignant.

Capsules.—The capsule, virtually, is a continuation of the fibrous lay of the periosteum. Like the periosteum it consists of two layers, an outer fibrous and an inner cellular. The outer fibrous layer is known as ligament, the inner cellular is the synovia. While they are not different structures, but simply continuations of the same structure, it is convenient for the purposes of x-ray pathology to consider them apart. The synovia is active, the ligament passive. It is a matter of great aid to visualize the ligament as being periosteum, and the synovia as marrow.

Synovia.—In its simplest form, the synovia represents a layer of round cells lining the capsule of the joint. For most of its extent it is smooth; but in the recesses of the joint it is thrown into false villi. When an inflammatory process invades the synovia, the round cells proliferate sometimes enormously. This accumulation of cells conduces to a general villous proliferation. Proliferation of this form is found in tuberculosis, in other infectious processes and in mechanical irritations to the joint cavities.

Ligament.—The ligament is the fibrous layer of the periosteum forming the capsule of which the synovia is the cellular layer. The only x-ray sig-

nificance that attaches itself to the ligament is its general configuration. From the bulging of the ligament an increase in the volume of joint-fluid is inferred.

CHARACTERISTICS OF BONE DISEASE.—In dealing with bones it is ever to be remembered that the morbid process runs its course in the marrow, locked up in the firm rigid casing or shell. The effects of the disease are rendered manifest upon this shell, which changes in the shell must not be regarded as the disease itself, but only as the effect of disease. In children there is the additional feature of the epiphyseal cartilage, which may influence the spread of disease.

CLASSIFICATION OF OSTEOPATHIES.—Following the classification proposed by Barker, osteopathies may be conveniently subdivided into the following groups: (I) The congenital osteopathies; (II) The degenerative, the toxic, and the endocrinopathic osteopathies; (III) The osteopathies of circulatory origin; (IV) The inflammatory osteopathies; (V) The neuropathic osteopathies; (VI) The parasitic osteopathies; (VII) The neoplastic osteopathies.

Congenital Osteopathy.—The congenital absence of bone is a matter of immediate recognition in x-ray pathology. Roentgenology is the most satisfactory method of investigating bone defects of all sorts. Two particular bone defects require special mention. First, in determining the presence of a cervical rib by x-ray study, it is important that the precaution be observed to ray the entire spine. Occasionally one finds variations from the normal. There may be seven cervical, twelve dorsal, and five lumbar; or eight cervical, twelve dorsal, and four lumbar. When there is a variation of more than one spinal element the tendency is to induce an abnormal visceroptosis. Visceroptosis is more apt to be present when there are four lumbar vertebrae than when there are five. There is but one positive means for determining the presence of cervical ribs, that of x-raying the entire spinal column. This is especially necessary when the cervical ribs are double.

Two types of vertebral abnormality may exist, the incomplete development of an existing vertebra, affecting the seventh cervical, the first dorsal, the fifth lumbar, and the top of the sacrum; and the actual development of an additional vertebra, rudimentary in type.

The transverse process of the seventh cervical vertebra is rudimentary. The processes get larger down to the fifth lumbar, where they are quite marked. If the laminae fail to unite, the condition is spina bifida. Ordinarily the laminae unite and form a spinous process. Occasionally, the spinous process may be formed from one lamina and mistaken for a fracture. The most common sites of rudimentary spina bifida are the seventh cervical, first dorsal, fifth lumbar, and top of the sacrum.

An abnormality with little significance is one involving the top of the sacrum. There may be either partial or complete sacralization of fifth lumbar vertebra. Instead of a perfectly straight transverse process, the fifth lumbar vertebra may show a bulbous end. No particular significance attaches itself to this condition; it is simply a peculiarity pertinent to the fifth lumbar vertebra to assume the characteristic of the top of the sacrum.

The x-ray diagnosis of sacroiliac subluxation is a matter of speculative conjecture. It is difficult to understand how the character of the sacroiliac synchondrosis would permit of a subluxation; and any slight sprain in the region of the synchondrosis might not affect the bony relations sufficiently to register on the x-ray plate.

Variation in the Bones of the Hand and Foot.—Dwight has very exhaustively dealt with the variations of the bones of the hand and foot. In a recent survey in which twenty-five thousand x-ray plates of the wrist were examined, the more common variations in the bones of the wrist could be plainly elicited on the x-ray plate. This is particularly true of the os magnum and scaphoid. In another series of sixteen thousand x-ray plates of the foot, there was twice encountered an abnormality of the pedal scaphoid, which appeared in a divided condition. The separated fragment detaches itself from the anterior upper surface of the pedal scaphoid.

With constant regularity in the forty-one thousand plates examined it was observed that the bones of the wrist or of the ankle were either of normal contour, or, if variant, the variable was never single but always multiple. So constant was this observation as to make for the formulation of a law called the "law of multiple variants."

The "law of multiple variants" has an extremely practical application. In a given examination, if a divided scaphoid is to be studied to determine whether the division is congenital or recent fracture, if tendencies to variation in other carpal bones are noticeable, the law of multiple variance would point to a congenital condition, always granting that the clinical history concurs. If, in the same case, no other variations are noticed in the carpal bones, the law of multiple variance not being sustained, the inference would be for an acquired trauma rather than a congenital defect.

Degenerative, Toxic, and Endoeritropic Osteopathies.—When the nutrition of a bony part is impaired, the changes that indicate the deviation from the normal are accompanied by variations in the radiopacity of the bone. Radiolucency is observed as the result of mineral absorption. Radiolucency occurs much earlier and more quickly than changes which induce radiopacity. Radiopacity results from the extra deposition of mineral matter or from the appearance of a new bony growth.

It may be gathered generally that acute bone disease is made evident by a change from radiopacity to radiolucency; and that chronic bone disease is made manifest by an increase in radiopacity.

Osteoporosis.—Should a muscle or a part be kept at rest for any considerable length of time, the bones in that part lose some of their calcium. The mineral is absorbed by the marrow where it comes in contact with the bone; so that, in effect, the marrow spaces everywhere become greater than normal. The bone assumes a more marked porosity and the condition is known as osteoporosis. It is important to recognize that in osteoporosis, or bone atrophy, the bone is not affected in radiopacity. Such bone as remains maintains its normal radiopacity; simply the Haversian spaces together with the trabeculae in general, exerting their demineralizing action through the marrow, occasion a more porous bone structure. This is to be con-

trasted with the actual radiolucency that involves a bone attacked by tuberculous infection, to be subsequently described.

Rickets.—Rickets is a common disease among young infants. It may be of fetal origin and consequently it may occur at any time. In this connection it is to be differentiated from scurvy which never occurs in utero, but generally occurs during the very early days of growth. The skeletal changes that dominate in the clinical picture of rickets consist of: (1) Softening of the bones with a lowering in their content of lime salts leading to abnormal curvatures; (2) Loss of bony substances; (3) Thickenings due to deposits upon the bones or to swelling of the epiphyses; (4) Disturbances in the longitudinal growth of the bone.

Rickets is characterized by a definite change in the epiphyseal line but not in the joint surface proper. All the disturbances occur at the epiphyseal line where there is an absorption and a softening of the bone. Hemorrhages extend into this area so that the growing cartilaginous structure is riddled. The area between the epiphysis and diaphysis becomes softened and putty-like. With muscle spasm these bony surfaces are approximated, the pressure causing the softened area to yield, producing a flaring-out. With the changes in the joint, in which the flaring-out extremity of the diaphysis is prominent, a marked absorption of calcium salts in the remaining portion of the bone becomes noticeable. The absorption affects all of the bone tissue; so that, differing from bone atrophy in which only the edges of the bone are demineralized, in rickets all of the bone is demineralized and assumes a radiolucency. The radiolucency may become so extreme as to make it difficult to distinguish between the shadow of the affected rachitic bone and the surrounding soft tissue. When the bone reaches this condition it becomes excessively pliable and prone to fracture. It is not uncommon for multiple fractures to occur; ten, twelve, and even as high as seventeen fractures having been seen in one case.

Periostitis may occur in rickets but is not common. It seldom occurs when the absorption of lime salts has been great.

It is advisable to examine the chest, in cases of rickets, where the cupping of the sternal attachment of the ribs is readily demonstrated. It is a reproduction on the plate of the "rachitic rosary" felt by the clinician.

On either side of and just beyond the shadow of the heart and aorta, a radiolucent band in the lung may sometimes be observed. It results from a direct pressure of the expanded ribs bearing on the lung surface and producing a line of atelectasis. It is pathognomonic of rickets.

The delayed bone formation, affecting particularly the cranial bones, is an added sign of rickets.

In summary, the x-ray pathology of rickets is manifested by halisteresis conducive to bone radiolucency; periarticular swelling; changes at the epiphyseal line producing mushroom flarings; fragility leading to fractures; occasional periostitis; the atelectic pulmonary band; and the rachitic rosary.

Scurvy.—The x-ray pathology of scurvy centers in and around the joint. Those changes that register occur directly behind the epiphyseal line on the

diaphyseal side of the epiphysis. A white line just back of the epiphysis in the shaft margin is the earliest evidence of the presence of scurvy. The line is thin, more radiopaque and more sharply defined than that occurring in rickets. Overlaying this line there is a radioparent space, or black line in which the bone has been nearly completely removed and only detrital fibrous tissue remains.

As soon as the eburnated radiopaque zone appears periosteal changes generally occur. Hemorrhages frequent the cellular periosteal layer. The hemorrhages are irregularly located at first; so that periosteal elevation of irregular and unequal distributions are found associated with the eburnated zone. At times the hemorrhage may invade the space between the epiphysis and the diaphysis, and its volume may be such as to occasion a separation of the epiphysis. The fibrous layer of the periosteum is generally stimulated to proliferation. In addition to being raised by the infiltration of blood into the cellular layer, the fibrous layer of the periosteum thickens and thereby becomes radiopaque.

Inflammatory Osteopathies.—Inflammation may involve the marrow contained within the bone and affect its changes on the surrounding bone, when the condition is known as osteomyelitis; or it may involve the cellular and fibrous layers of the periosteum when the condition is known as periostitis. In general, from the viewpoint of x-ray pathology two types of inflammation may be recorded; those due to usual organisms, including staphylococci; or, organisms like typhoid bacillus and pneumococcus that produce changes in the marrow that cannot be differentiated from those produced by pyogenic organisms. Then, there are the inflammatory reactions that are due to an invader by syphilis or tuberculosis, which invasion produces a somewhat distinctive x-ray pathology and which is called, clinically, specific inflammation.

Acute Osteomyelitis.—In the order of frequency, the common sites for osteomyelitis are the shaft of the femur, the clavicle, scapula, a rib and a tibia. This is particularly true when the infection is primarily the result of a hematogenous origin; but any bone may become involved, including the flat bones of the skull, the spine, the sternum or the small bones of the extremities. The inflammatory agent exerts its effect upon the bone matrix through the elaboration of toxic products that become diffused in the marrow of the affected region. In the case of pyogenic organisms, and also typhoid bacillus and pneumococcus, the first effect of the presence of suppurative products is to induce on the surface of the bony framework that includes them an overdeposit of lime salts. This deposit encroaches on the adjacent spaces and give the appearance of eburnation. It cannot be recognized on an x-ray plate unless the radiograph is enlarged some three or four times. The sign is generally overlooked in spite of the fact that it is an early and only x-ray evidence of acute osteomyelitis in the very first stages.

As the osteomyelitic process continues, the sclerotic lining of the bone spaces disappears; the bone being replaced by bone absorption, a condition formerly recognized as halisteresis. If an enlargement of a suspected bone area fails to show a sclerosis of the margins of the bone space, the x-ray

inference may be that no infection is present, or that if infection is present, it has passed the very incipient stage and has begun to occasion necrosis. Necrosis may progress rapidly and circumscribed and produce a bone abscess; or it may effect the necrosis of a diffused mass of bone leaving sequestered areas with sequestra *in situ* and perpetuate chronic suppuration with sinus formation. It is seldom that acute osteomyelitis is diagnosed from the x-ray plate unless it has reached the stage of abscess formation or until a considerable area of bone has been attacked. Periosteum is never visualized on an x-ray plate unless it has undergone a change accompanied by the infiltration of radiopaque or radiolucent material, generally calcium salts. Osteomyelitis, when purely of a hematogenous origin, is usually medullary. When it results from trauma it is more generally cortical. Cortical osteomyelitis is characterized by a marked production of periosteal bone. It is accompanied by periosteal swelling, the cellular layer of the periosteum being engorged with purulent products of inflammation. It is extremely important to remember that bone deposition following osteomyelitis is on the osteal side of the periosteum; never in the soft tissues. If bone growth or deposition is found in the soft tissues, the pathology is not osteomyelitis but is more probably an osteal growth or a form of myositis ossificans. There is an inverse proportion between the acuity of osteomyelitic infection and the deposition of calcium salts. In the early stages and when the acuity is highest, lime salts are resorbed; in the later stages and as the process assumes a chronic character calcium salts are deposited.

Chronic Osteomyelitis.—The peculiarities affecting inflammations in bone are two; one anatomical and the other physiological; the former resides in the structural arrangement of bone wherein the essential protoplasmic element with its bloodvessels is enmeshed within the walls of a rigid, non-vital mineral framework; the later, physiological, resides in the special activities and powers possessed by this vital element in two opposite directions, that of gradual absorption of the rigid element which surrounds it, and that of stimulating additional deposit of mineral salts. It is to this second peculiarity that two pathological processes, osteoporosis or caries, destructive and rarefying, and osteosclerosis, defensive and reparative, result.

Necrosis.—When an appreciable amount of bone dies it undergoes necrosis. Necrosis is gangrene of bone tissue and applies to the death of any microscopic quantity of bone. Death affects only the vital cellular elements, the inert matrix undergoing no immediate change. All the changes that occur in the matrix are secondary and subsequent to the necrosis, forming no essential part of the gangrene. Caries is a gradual, progressive process varying with the character and intensity of the irritant. When the infectious agent is of such virulence as to occasion degenerative changes in the bone forming cells, caries results in destruction of all of the elements of the bone; but where, on the other hand, the irritant agent is avirulent, or the infective agent is of subminimal level of intensity, the carious process consists merely of rarefaction incident to an absorption of the bone matrix alone.

Cavity Formation in Bone.—Cavities may be classified according to an etiological, a pathological, or a bacteriological basis. J. Renfrew White gives the following classification:

1. Aseptic cavities of traumatic origin. (a) The aseptic cavities of simple fractures. (b) The cavities left after the removal of an aseptic foreign body. (c) The cavities left after the removal of new growths of bone.

2. Aseptic cavities of spontaneous origin. (a) The cavities due to new growths. (b) The cavities of fibrocystic disease of bone.

3. Infected cavities of traumatic origin. (a) Cavities the result of the presence of an infected foreign body in bone. (b) The cavities of compound fractures proper, either before or after the performance of simply sequestrectomy.

4. Infected cavities of spontaneous origin. (a) Cavities the result of chronic spontaneous (hematogenous) osteomyelitis. (b) Cavities the result of acute spontaneous (hematogenous) osteomyelitis.

In some cases, as in fulminating osteomyelitis, destruction beginning in a small focus spreads so quickly as to preclude the x-ray differentiation from a malignant bone disease. Osteomyelitis may, with practically no new bone production, produce a vacuolated area in the shaft of the bone. Bone destruction may increase and the cortex be broken through. This breaking through releases the tension produced by the accumulating suppurative products; but the destruction, after the breaking through is accomplished, does not penetrate the opposite side of the shaft. This is a differential distinction from the x-ray pathology of malignant growths wherein breaking through is multiple and often involves both sides of the shaft. The moment the bone is broken through and the suppurative products are released there, bone production begins. Bone production follows the stimulus of an irritant; and osteomyelitis acts as an irritating agent. The locus of stimulation is practically always confined to the junction of the normal bone with the infected bone. Chronic osteomyelitis is characterized by a thickening of the bone which gives an appearance of increased radiopacity. The appearance is due not so much to an additional deposit of new mineral in the already existing bone, but more to an obliteration of the radiopaque marrow spaces. Mineralization proceeds at the periphery of the shaft, where it is more or less confined by the protective periosteum, but it advances rapidly in the medullary region, where the existing marrow channels offer less resistance to the deposit of mineral than does the protective periosteum. The effect is to obliterate the medullary canal. In the x-ray pathology then, a general enlargement of the bone, a more radiopaque structure and a tendency approaching completeness to obliteration of the medullary canal, all are x-ray signs of chronic osteomyelitic involvement.

Acute Periostitis.—Acute periostitis may follow trauma or infection. It is not uncommon as a complication in typhoid fever, in which infection the acute periostitis involves the tibial periosteum and sometimes the periosteal covering of the clavicle. The cellular layer of the periosteum is invaded by organisms that engorge the cellular periosteal space. If the resistance of the cellular periosteum is greater

than the infecting force, the products of infection neutralization accumulate in the cellular periosteal layer, raising the fibrous layer and giving the x-ray appearance of a radiolucent mantle surrounding the bone shaft; but if the infection is of great virulence, and the cellular periosteal reaction is of subminimal resistive capacity, the cellular elements are attacked and destroyed, a partial liquefaction necrosis ensues and the necrotic products distend the cellular periosteal space with a material that is more radiopaque than the normal radiolucency of the fibrous periosteal layer. In each case, the fibrous layer is elevated and separated further from the bone by the swollen cellular periosteal mantle. In successful immunity, the cellular periosteal space is radiolucent; in unsuccessful immunity, or progressive infection, the cellular periosteal layer becomes more radiopaque.

Chronic Periostitis.—In chronic periosteal inflammation the fibrous layer may thicken and become radiolucent, at times radiopaque; while the cellular layer may occasion an infiltration of mineral salts both in itself and also into the fibrous layer. The x-ray pathology is evidenced by a periosteal radiolucent or radiopaque mantle surrounding the shaft but less radiopaque than the shaft. Ordinarily, the bone deposit in the fibrous lamellae is striated and is deposited in superimposed layers growing usually by centrifugal accretion.

Bone deposition is the result of an irritant stimulus and proceeds, regardless of the origin of the stimulus able to produce it, in an identical manner; it is, therefore, barely possible to distinguish the various stimulants that occasion a periosteal chronic inflammation. There is an exception in the case of periostitis due to syphilis. When of luetic origin, periostitis may assume its usual form; but occasionally the deposition of lime salts in the periosteal tissue is irregular and unevenly distributed. The result is a "lace-like" appearance of the elevated periosteum. When it occurs, this lace-like periosteal reaction, serrated or tooth-like, is so typical of syphilis as to make it practically an infallible x-ray sign distinctive of syphilis. No other form of periosteal infection manifests itself in this way.

Chronic Pulmonary Periosteopathies.—In some pulmonary conditions, and occasionally in tuberculosis and in sarcoma, the fibrous layer of the periosteum thickens and becomes radiolucent or radiopaque, depending upon the amount of thickening. The cellular layer widens and elevates the fibrous layer. The x-ray pathology is that of a radiopaque "hair-line" elevation separated from the bone by a markedly radiopaque space. The x-ray appearance is difficult to differentiate from that of acute or subacute periostitis of virulent infection in the initial stages. Chronic pulmonary periosteopathy affects particularly the long bones. It can be distinguished from acute suppurative periostitis by the fact that chronic pulmonary periosteopathy is multiple and affects all the long bones, while suppurative periostitis is usually localized, involving only one bone or part of one bone.

Syphilitic Osteopathy.—In x-ray experience, syphilis manifested in children is generally congenital; that manifested in adults is usually acquired. It is rare if ever that acquired bone syphilis is

found in children. When syphilis invades a joint the capsule is swollen with fluid and periosteum at the junction of the periarticular cartilage is thickened. In children this is accompanied by more important changes in the bone itself at the epiphyseal line. There are erosions at the side and edge of the epiphyseal line on the diaphyseal side. This erosion is accompanied by a periostitis with rarely occurring superperiosteal hemorrhages, by which it is distinguished from scurvy. The lesion in syphilis is multiple. Syphilis is a stimulant to mineral deposition. The deposit of lime salts is manifested under x-ray pathology by the marked calcific infiltration invading the periosteum. There is no infectious irritant that induces as much bone deposition as does syphilis.

In secondary syphilis the superficial bones (skull, anterior surface of tibia, ulna, and metacarpals) are most often affected. Superperiosteal deposits of mineral, giving rise to syphilitic nodes, become clinically palpable and readily visualized under x-ray examination.

In tertiary syphilis, gummata appear. These may be either in the form of circumscribed periostitis, causing round nodes, or they may begin in the marrow and in the spongy part of the long bones. Occasionally a phalanx may be affected as in dactylitis syphilitica, or a metacarpal bone may suffer luetic invasion giving rise to an appearance very much resembling the appearance produced by a tuberculous "spina ventosa."

Tuberculosis.—In bone, tubercle manifests itself chiefly by a markedly increased radiopacity of the structure. In children, the order of frequency of bone lesions is (1) Rickets, (2) syphilis, (3) Scurvy. Tuberculosis is said not to occur in children under one year of age. The claim is made that it requires nine months for tuberculosis to develop sufficient changes to be recognized in the form of x-ray pathology; and since it is further maintained that tuberculosis can not occur in utero, obviously about a year forms the first period in the age of the child when tuberculosis can be sought in the bones. More generally, it seldom appears before the second year. Tuberculosis is distinguishable in that tubercle produces halisteresis. At the site of lesion in the bone all grades of radiopacity are observed from a slight change to extensive areas of rarefaction, even necrosis or cavity formation. The rarefaction is the result of a resorption of mineral. This resorption proceeds with great rapidity and is marked by the fact that the lime is withdrawn from the bone and is apparently transferred to the marrow for transportation elsewhere; but while in the marrow it remains in an insoluble form, and therefore renders the radiopaque marrow spaces radiopaque. In this fashion, the added radiopacity in the marrow spaces, together with the increased radiopacity of the mineral matrix make for a rarefaction characterized by diffuse indistinctness of outline. The analogy has been made, for the purposes of imaginative illustration, to the effect produced by drawing the outline of a bone with chalk on a black-board and gently rubbing the sketch with a soft cloth, the general haziness and obfuscation resulting simulating a bone invaded by tuberculosis as revealed on the x-ray plate.

If the lesion is in the neighborhood of a joint,

additional changes are superadded. In the region of the joint there are two lymphoid structures, the red marrow and the synovia. Red marrow occurs also in short and flat bones, vertebrae, sternum, cranial diploe, carpi, tarsi, and so forth; and it is to be noted that, wherever red marrow occurs, the bone is vulnerable to tuberculosis. Contrariwise, when a bone region is free from red marrow, tuberculous invasion is not found. Tuberculosis localizes in the red marrow of the bone and of the joint. In itself tuberculosis does not produce bone. Bone is only produced when there is a concomitant infection. The synovia is greatly affected in tubercle. Unless a secondary infection is present no new bone is produced; but the mineral is withdrawn from the adjoining non-vital matrix and is thrown into the fluid of the joint, where, remaining as an insoluble suspension, it renders radiopaque the normally radiopaque joint fluid. Says Edward W. H. Shenton:

Instead of the clear outlining of the bones and their cancellated structure, a fluffy effect is seen, the outline being blurred and the cancellous tissue difficult of detection. The unskilled will observe "what a pity the photograph is not clearer," and one has learnt to regard this criticism as a strong confirmation of a diagnosis of tubercular disease in joints (as well as in certain other situations spoken of later). This blurring is due to fluid in part, but also to thickened synovial membrane, the fluid in the case of tubercle being much less than in simple acute arthritis. An acute or sub-acute arthritis may show a greater degree of blurring than early tubercle, and unless clinical evidence is very definite a simple and a tubercular arthritis may be confounded. It is not often that the mistake is made. A careful examination of the surrounding bone tissue will help to confirm or disprove a suspicion of tubercle.

Paget's Disease.—It is seldom that Paget's disease is visualized in persons under 40 years of age. The symptoms develop clinically with pains and enlargement of bone. There are instances in which the onset is insidious, and the deformity of the bone structure is the only change at first recognized. In the order of frequency, the bones affected are: Skull, tibia, femur, pelvic bones, spine, clavicles, ribs, radius. The disease may or may not be bilateral. In the bone the pathology consists of a softening and a pathological swelling in the longitudinal direction on the convex side. This swelling is at the expense of existing matrix, the marrow spaces becoming widened. It may be compared to a bone emphysema. Its x-ray pathology is manifested by long longitudinal areas of radiopacity.

The changes in the skull closely approximate those seen in hydrocephalus, the entire head assuming the form of a triangle, base upward. The frontal bone projects. In the swollen skull there are irregularly distributed areas of radiopacity. Baetjer characteristically describes the x-ray pathology of the skull in Paget's disease by the effect in the kinks of a negro's skull impregnated with calcium salts.

In the extremities, calcified arteries are somewhat characteristic, or at least marked features of Paget's disease. The technology for the exposure of a knee as described by I. Seth Hirsch is useful in demonstrating a calcification of the popliteal arteries in the popliteal space ("Principles and Practice of Roentgenological Technique," I. Seth Hirsch, page 173). There are certain changes in the base line of the skull to which Leri has sub-

scribed a special formula. The x-ray pathology of Paget's disease is sufficiently recognizable without the use of base-skull measurements.

Neuropathic Osteopathies.—Syringomyelia of the Morvan type is recognized by a gradual disintegration of a finger tip. In other forms syringomyelia always involves a joint. The changes affecting a joint in cases of syringomyelia are difficult to distinguish by x-ray pathology, from Charcot joint. In the Charcot joint, however, there is more bone destruction and more detritus present than in syringomyelia.

Raynaud's Disease and Leprosy.—Raynaud's disease and leprosy give a pointing of distal phalanges. Raynaud's disease usually fails to show any signs until it has gone on to gangrene.

Parasitic Osteopathies.—Parasitic osteopathies are rare. An echinococcus cyst has been described within a bone. Amebic necrosis of bone has sometimes been found to occur in cases following pyorrhea alveolaris. It is obvious that in these cases the x-ray pathology would be that of a bone cavity already discussed under the classification previously given by White.

Neoplastic Osteopathies.—Fibromata occur most commonly in the periosteum of the bones of the head and face. They are apt to form polypoid tumors projecting into the antrum of Highmore. Fibromata are generally loose textured, and may undergo some calcific changes, when they appear as radiolucent tufts with circular parallel fibers that are distinctly radiopaque.

Central fibromata are rare. Their most common seat is the inferior maxillary bone. Maxillary medullary fibromata are exceedingly prone to calcification. They may even ossify. Sometimes, fibromata undergo sarcomatous changes.

Chondromata.—Following a fracture, the periosteum may become invaginated between the fragments and a portion may give rise to cartilage growth. Or, according to Virchow, there may be an aberrant cartilaginous nidus that remains unossified in an epiphysis; and as the epiphysis progressively grows, the nidus remains isolated. At some later time, cartilaginous proliferation is stimulated in the nest, and a cartilaginous growth proceeds.

When the growth is near the cortex, the growth may project into the soft parts; but it remains attached to the bone by a very broad base. If the growth is medullary, the cortex simply expands to accommodate the cartilage nodule. It is not until the growth expands the normal contour of the bone that includes it, that it is objectively appreciated by the patient; so that chondromata are detected in young adults, though they are most often congenital and appear more frequently in young people than might be thought. In 250 youngsters, twelve years of age and less, rayed at random, three cases of chondromata in the manipalanges and one case in the pediphalanges, were observed.

Chondromata affect multiple bones in one individual, generally phalanges. A form of chondroma, more calcified than the commoner variety, develops beneath the periosteum in the femur and tibia near the knee joint, giving the bone a club-shaped enlargement.

Their x-ray pathology is characteristic. When

pure, they show as hyaline radiolucent areas quickly contrasted from the surrounding bone and entirely free from structure. If they have suffered trauma, they may calcify. The tumor matrix is less radiolucent in proportion as the calcium phosphate and carbonate precipitates its colloidal particles. The precipitation may go on to complete radiopacity. In the more fibrous chondromata, the calcific infiltration may orient itself according to the fiber distribution of the cartilage and radiopaque whorls become manifest.

While chondromata appear electively in the phalanges and tibial and fibular heads, any bone in the body may be the seat of these tumors, excepting the skull, ribs, scapula and only very rarely in the spine. These tumors may become sarcomatous.

Osteomata.—Bone outgrowths as a result of inflammatory processes are common. While they are not, strictly speaking, tumors, some of their forms are closely allied to them and can be conveniently considered under that head.

New growths of bone arising from surfaces are exostoses if the origin is external, enostoses if internal. They may contain all the elements of bone; bone proper, medulla, vessels, periosteum and cartilage. The new bone may be compact and ivory like (eburnate), or spongy and cavernous, the spaces being filled with marrow.

Small, sharp, narrow, spiculated processes, occurring in connection with periostitis, are osteophytes.

Polypoid, or large rounded tumors, may be seen. The bone may be enlarged and its surface greatly roughened, a condition called hyperostosis. Beneath these new growths the bone may appear normal, radiopaque (due to sclerosis) or radiopaque (due to rarefaction). In instances, the medullary canal of the bone may communicate with that of the exostosis.

Exostoses develop usually from the periosteum, sometimes in the insertion of tendons and ligaments. They are nearly always multiple and may occur at all ages, including even uterine life. Chondromata are multiple in the sense that many bones are involved in the same case; osteomata are multiple in that the same bone may show numerous osteomata. Exostosis occur near the joint, and, singularly, always point away from the joint to which they are nearest.

Enostoses develop in the interior of bones, apparently from the medulla. They increase in size, absorbing the surrounding bone as they grow until they project from the surface like exostoses. Enostoses are rare, affecting mostly the bones of the cranium and face. In cases, when an exostosis is viewed through a long bone, its relation to the superimposed tissue is such as to give the appearance of a growth in the medullary canal.

Ossifying Hematoma.—Hematoma result generally from trauma. In young adults and adults, they are most common in the femur; in infants, the cranium is involved, the hematoma occurring two to four days following delivery, undergoing calcific infiltration up to one year, during any time of which calcifying process, ossification may ensue.

In adults, it may be mistaken from its x-ray appearance with sarcoma. The bone is deposited parallel to the shaft in ossifying hematoma; and in

no malignant bony tumefaction is this order of bone deposition visualized. This differential is significant. Also, in hematoma, ossification proceeds from the periphery inwardly, or centripetally. Ossifying hematoma has a definite border.

Bone Cysts.—These occur in and near the epiphyseal line, their origin being quite similar to that of chondromata, with which they are readily confused. In tumor pathology of bone, cyst cases occur once to 98 cases of chondromata (series 6200 bone tumor cases, cysts found 3 times, chondromata 294 times), when they were preceded by a definite history of perforation by bullet in two cases, and osteomyelitis in the third case.

True cysts are found most frequently in the maxillary bones in connection with teeth. Here they may be unicellular or multilocular. They begin in the medullary portion and increase in size, distending the bone as they grow.

Occasionally, dermoid cysts are found in connection with skull bones.

General Discussion of Tumor Pathology.—When typical, the condition just discussed offer little difficulty in recognizing them on the x-ray plate. Diagnostic acumen is necessary in distinguishing the various malignant tumors that may arise in bone, or in differentiating a malignant from a benign growth when the latter is atypical.

Malignancy of a growth is established if invasion can be demonstrated by the x-ray. Invasion is the destructive progression of a new growth characterized by the complete replacement of all tissue in the path of the procession. Invasion follows a rapid growth during which there is no opportunity for bone production. Invasion irradiates in all directions; but it may be more generally cortical or more generally medullary.

Tumors of cortical origin may be:

<i>Malignant</i>	<i>Benign</i>
Periosteal sarcoma	Ossifying hematoma
Osteosarcoma	Osteochondroma

Those of medullary origin may be:

<i>Malignant</i>	<i>Benign</i>
Sarcoma	Osteochondroma
Carcinoma	Cysts
Osteosarcoma	Giant cell sarcoma (?)

Having determined the origin of the tumor, whether cortical or medullary, it is imperative that the question of bone production be established. In studying bone production, the direction of bone deposition in relation to the axis of the bone must be ascertained. Bone production may be parallel to the shaft of the bone, or irregular and more generally perpendicular to the axis. According to bone production, tumors may be classed as—

<i>Irregular bone-producers or Malignant</i>	<i>Parallel bone-producers or Benign</i>
Periosteal sarcoma	Osteoma
Osteosarcoma	Osteochondroma
	Hematoma

No malignant tumor of medullary origin is a bone producer; so that if a tumor is demonstrably medullary in origin, and its tendency is to bone production, malignancy is ruled out. Medullary tumors that do not produce bone, or malignant, are

Sarcoma
Carcinoma
Giant cell sarcoma

Of these, sarcoma and carcinoma destroy the cortex; giant cell sarcoma generally leaves the cortex intact.

In the x-ray analysis of tumor pathology one determines: (a) Origin; whether cortical or medullary. (b) Bone production; whether present or not present. (c) How bone is deposited; centripetally or without arrangement. (d) Cortex; whether destroyed or intact.

The following chart shows the tabulated analysis: **Sarcoma.**—Sarcoma is especially common in bones, affecting young adults. It may be primary or metastatic. It may grow from the cellular layer of the periosteum, or from the medullary layer.

ANALYSIS OF X-RAY PATHOLOGY OF TUMORS.

ORIGIN	Cortical	Bone Producer	Parallel to Bone	{ Centripetal parabola Hyaline matrix	Ossifying hematoma (B) Osteochondroma (B)
			Helter Skelter	{ Disarranged and undelimited Tendency to metastases	Myositis ossificans (B) Osteo sarcoma (M)
		Non Producer		Purely hyaline	{ No metastases
					Peripheral enchondromata (B)
	Medullary	Bone Producer	Hyaline Bone after trauma	Chondromata (B)	
				Non Producer	Cortex intact
		Cortex destroyed	Adults		
				Young adults	Sarcoma (M)

M—Malignant. B—Benign. ?—Questionable malignancy.

Periosteal sarcoma commences in the cellular layer of the periosteum, pushing outward the fibrous layer. After a time, the fibrous layer is involved and the tumor invades the surrounding soft parts. The cortex beneath may remain normal, or it may be eroded and gradually disappear until the tumor is continuous with the medulla. The origin is never medullary, however; and the tumor may attain great size without producing a visible change in the cortex. Bone production is seen, the growth of new bone usually taking the form of plates or spicules, radiating outward—an appearance fancifully described as the "setting sun rays."

Periosteal sarcoma occurs near a joint and can be mistaken, in certain stages, for an arthritis. It is fundamental to remember, however, that malignancy does not involve a joint. In x-ray pathology, a lesion that ultrapasses a joint is other than malignant. This rule seems infallible. Periosteal sarcoma affects young persons, between puberty and middle age, and favors the femur near the knee.

There is a mixed form of tumor, osteosarcoma, which is prone to spread and to form metastases. If it grows rapidly, it may produce little bone, if slowly, much bone may be formed. Osteosarcoma might be mistaken for osteomyelitis, from which it is differentiated by the fact that osteomyelitis never produces bone out in the soft tissues; and osteoma, which latter is generally smaller, more eburnated and usually multiple. Osteosarcoma distinctly invades, sweeping the cortex away in many places.

Giant cell sarcoma originates in the medullary portion of the bone. It expands in every direction, like a malignant growth, but is more limited. Its favorite site appears to be radius and tibia. It does not produce bone. When there is cortical expansion, the cortex is smooth and symmetrical, not nodular.

Spindle and round celled sarcoma begin in the medulla. No bone production accompanies these growths. They radiate equally in all directions and distinctly invade the cortex. Their x-ray pathology is closely allied to the appearance given by carcinoma. Age of the patient and location of the growth may make probable a differential inference. Sarcoma is generally singular, carcinoma, multiple.

Carcinoma.—It is questionable whether carcinoma can arise *de novo* in bone. Nearly always it is a metastatic invader of bone. Being conveyed by the lymph channels that accompany the nutrient vessels through the nutrient foramen, carcinoma is more apt to localize in the region of the nutrient artery inlet.

Carcinoma is generally circular in character. It does not expand the cortex, but invades and destroys it. Excepting in the case when there is a sacral metastasis from the prostate, when, owing to irritation, bone is produced, carcinoma occurring in other locations is a non-producer of bone. The femur, pelvis, spine, humerus, and bones of the head are more commonly, in the order named, attacked. The scapula and clavicles are more rarely invaded. Extremely rare invasions of the tibia are met; and the bones of the hand and foot have never been recorded as carcinomatous.

Distinction between carcinoma and sarcoma is

difficult from x-ray pathology. The site and the age of the patient may suggest the probable character of the tumor.

The important factor in bone diagnosis of tumors is less to decide the exact histopathological character of the growth than to determine whether or not the tumor is malignant. As in the microscopic histology, malignancy is inferred in a measure from the contour and limitation, so in the x-ray pathology the limiting surface of the tumor may suggest malignancy or not. In general, if the limits of the bony outline of the growth are broken through, trauma being excluded, malignancy is assumed. Malignancy is especially suspected if invasion is established.

Probable Tumors in Various Sites.—In reviewing 4800 bone tumors, the exact character of which was established by histopathologic section in each case, x-ray pathology of tumors gave the following favorite sites for each type of tumor.

TABLE OF BONE TUMOR INCIDENCE
(Study of 4800 x-ray cases of bone tumor clinically corroborated)

LOCATION	TUMOR	REMARK
Highmore's antrum	fibroma	benign
Lower jaw	1 cysts	
Spine	2 medullary fibroma	both benign
Cranium	1 metastatic carcinoma	malignant
	2 dermoid cysts	benign
	2 carcinomatous metastases	malignant
	3 sarcomatous metastases	malignant
Clavicle	1 sarcoma	malignant
Humerus: upper end	1 sarcoma	malignant
lower end	1 hypernephroma	malignant
Radius: upper end	1 exostoses	benign
lower end	1 giant cell sarcoma	doubtful malignancy
Phalanges	1 enchondromata	benign
Pelvic bones	1 carcinomatous metastases	malignant
	2 sarcomatous metastases	malignant
Femur: upper end	1 all forms sarcoma	malignant
	2 osteomatous growth	benign
	3 bone cysts	benign
	1 exostoses	benign
lower end	2 sarcomata	malignant
shaft	1 ossifying hematoma	benign
Tibia: upper end	1 sarcomata, giant cell	malignant
	2 bone cyst	benign

CONFESSIO FIDEI MEDICI.

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

It would be well to-day, in my judgment, for every practitioner of medicine and especially the younger men, to read "Religio Medici." If that charming companion, Sir Thomas Browne, could again come to life, he would surely inculcate many a useful lesson of mind and heart. But, alas; he can not. Sir Thomas Browne was not a great discoverer, or, maybe, very renowned as a mere healer of the body, but when we come to read and absorb his genial philosophy of life, we learn much of what best pertains to this world and indeed, his philosophy does not go amiss when we turn to things of the life beyond. Somehow in thinking of Sir Thomas Browne, I also think of the immortal Pasteur, not because they are at all in the same line as great discoverers. Pasteur was eminently one of these. Browne was not. When, however, it comes to what is the best, the lovable part of man, they were united, and their ideas and affections rose to heights far beyond what we meet with to-day, except in the rarest instances.

These reflections come to me as I think of the past in my profession as I knew it, and of what is ever present and evident to me to-day. Then it was, indeed, a hard calling in more than one sense. The practitioner had few luxuries and fewer distractions from his profession. He labored night and day, and at all hours, for his patients. Their welfare was his first thought; at times it seemed as if it were his single, absorbing one. And as to the pecuniary reward, that was usually a very minor consideration. Sacrifice of self and going about doing good were the delight and the essence of the old doctor's life.

The return to him, his reward, was the deep love and abiding faith and trust of his patients. In this was his splendid compensation.

How is it to-day? The past is gone. The present means the specialist with all his fresh, advanced ideas of practice. But is there much thought of self-sacrifice and devotion? Alas, no! It is time, money, ambition, ease, distraction, change, vacation—and in addition, big, not to say exorbitant fees for services rendered. This way of looking at things is not now, invariably, that of the city physician alone. The country doctor has imbibed it to a certain extent; indeed, so far as he is able. He must have time to rest and play his game. Of course he has his motor car and whenever it is desirable and at all possible, he takes a trip of several weeks to Florida, or to California, to renew his vigor and, surely, to add to life's pleasure. If he does not get what he wants legitimately he simply takes it. It may be that no other practitioner is left in the village during the cold, stormy winter months. He goes and that is all there is to it. Now, how do the patients think and feel about all this? Surely, of course. But what can they do? One thing they can do and it is this. They can give to the worthy, experienced country practitioner, if he will stay by them, such remuneration and such a comfortable home, that he will feel that his services are really appreciated, as they should be, and in that case he will not leave them in the lurch, but will stick by them—remain true, trustworthy and willing, and above all, most helpful to all in time of greatest stress and need. When the influenza strikes them and lays low many, young and old, he will be there helping, prescribing, doing, comforting—cooking if need be, and when the epidemic is over, they may well rise up and call him blessed. All little stories such as mine, should have an end—and a speedy one, too, if the moral rehearsed is to be graven within. I go to my lunch and thus exemplify my tale—perhaps, "peut-être oui et peut-être non!"

129 EAST THIRTY-FIFTH STREET.

Public Hospitals' Liability to Persons Other Than Patients.—The New York Court of Appeals holds that, within the rule a hospital, though public, is liable to strangers, i.e. to persons other than patients, for the torts of its employers committed within the line of their employment, a hospital corporation under contract to furnish a city with ambulance service under section 693a of the Greater New York Charter, added by Laws 1909, c. 395, was liable for injuries to a person in a taxicab sustained in a collision with the hospital's ambulance.—*Murtha v. New York Homeopathic Medical College, etc.*, 228 N. Y. 183, 126 N. E. 722.

REPORT OF A CASE OF POLYCYTHEMIA VERA (VAQUEZ'S OR OSLER'S DISEASE).*

By SAMUEL GITLOW, M.D.,

NEW YORK.

(From the Lebanon Hospital Dispensary.)

MRS. I. A., 59 years of age. A widow, born in Russia. Occupation light housework.

Chief complaints: Dizziness and giddiness, easy fatigability, and pains of a neuralgic character over various parts of the body.

Family History: Mother died at a young age, from a cause unknown. Father died at 65 years of age of asthma. The patient has one brother and two sisters, all of whom are alive and apparently well. Her husband died two years ago of a perirectal abscess, but had been well until then. She had two daughters, one of whom died at the age of five years of septic scarlatina; the other one is living and well.

Past History: Measles in infancy and smallpox as a child. There is no history of malaria, tuberculosis, or lues. The patient had no primary lesion or secondaries or miscarriages. She had pneumonia 16 years ago, which was followed by empyema (?) and recovery without operation. Six years ago she was at the Lebanon Hospital with a disease which was there diagnosed as influenza. She has never had a chronic cough, asthma, or chronic expectoration. She has never had any acute or chronic diarrheal disease, nor any condition of intermittent or persistent sweating.

Present History: This dates back two years or from the death of her husband. Her daughter noticed that the patient's face began to get ruddy and that this ruddiness gradually increased. At one time a physician who saw her asked how she had become so sunburned. Together with this she began to complain of much headache, dizziness, and giddiness. She became fatigued at the slightest exertion as well as dyspneic. Various paresthesias developed over her body, as well as an attack of severe pain extending back of the ears and down the neck. One year ago she had a fairly well defined attack of sciatica from which she shortly recovered and during which I saw her. At that time her face was not as markedly ruddy as now. With the development of all these symptoms there was an obstinate constipation, whereas formerly she had been very regular. She occasionally has colicky pains in the epigastrium, during which she always vomits bloody mucus. Her gums bleed at the slightest provocation and she has occasional nose bleed. Her menstruation was normal to the menopause of 44. Micturition is normal three or four times daily, none at night. There are no nervous manifestations. She sleeps fairly well. There is no history of jaundice or gall-bladder disease. She has very seldom taken coal tar drugs, never for any length of time.

Summary of History: The only etiological point in the history is the concurrence of the death of the husband with the onset of the symptoms. An emotional factor has been mentioned as a possible exciting cause of polycythemia.

Physical Examination: A woman past middle age, fairly well nourished. Face, neck, and hands markedly turgid. Lips of a cyanotic red hue. This ruddiness extends down the neck and well down on the chest and back. It also involves almost the entire arms, but does not extend over the abdomen or legs. The skin is extremely dry, more so at certain times than at others. The eyes are normal in appearance except for marked, almost cyanotic, injection of the palpebral conjunctivæ. The pupils react normally to light and accommodation. There is no nystagmus or other eye-signs. The mucous membrane of the mouth is markedly red and cyanotic, as is also the tongue. The teeth are in poor condition, while the gums are red and cyanotic and bleed at the slightest touch. There is no palsy of any kind about the face or mouth.

The thyroid cartilage lies well forward and gives the impression of general enlargement of the thyroid gland, which, however, has only the right lobe slightly enlarged. There are no other glandular enlargements in

*Presented at a meeting of the Bronx County Med. Soc. at Lebanon Hospital, April 21, 1920.

the neck, neither the anterior nor the posterior cervical chain being palpable.

The chest and abdomen are normal in appearance except for the redness over the upper part of the chest. There are no palpable glands in the axilla or in the epitrochlear region. The respiratory excursion is normal. Percussion and auscultation of the lungs yield nothing abnormal. The heart is enlarged slightly to the left, the apex being auscultated, percussed, and palpated about $\frac{1}{2}$ inch to the left of the mid-clavicular line in the fourth interspace. The right border of the heart is found by percussion at the right border of the sternum. The sounds at the apex are slightly muffled, but there are no adventitious sounds or irregularities. The sounds at the base are normal except for moderate accentuation of the second aortic sound. There is no dullness above the heart.

The abdomen is soft throughout. There are no masses to be felt. The liver and spleen are not palpable. The spleen is found on percussion to be normal in size.

The genitals and lower extremities are normal. There are a few enlarged glands in the groin but none elsewhere.

The ears are normal. The posture and gait are normal. There is no Babinski, Oppenheim, Kernig, or Romberg sign.

The blood pressure taken at two successive times was 150 and 140 systolic, and both times 100 diastolic.

The pulse is normal but is inclined to be full. The arteries are not palpably thickened.

The urine was examined and showed nothing abnormal.

The blood was examined twice. The first count yielded 6,500,000 red cells and 105 per cent. hemoglobin (Dare.). The white count was not made at this time. The second examination gave 6,740,000 red blood cells and 140 per cent. hemoglobin (Sahli). There were 14,000 white blood cells with 83 per cent. polymorphonuclears. The color index was 0.7 the first time and 0.9 the second.

Diagnosis: In the absence of anything that might cause concentration of the blood, such as diarrhea or profuse sweating and in the absence of residence at a high altitude, and because of the evident plethora, the condition is not one of relative polycythemia, but is absolute. In the absence of any signs of portal obstruction, of chronic cardiac or pulmonary disease, of impeded circulation, of an old malaria, or of tuberculosis, the case becomes one of primary erythremia and not of secondary absolute polycythemia or erythrocytosis. The spleen is not palpable in this case. Of some of the cases reported as erythremia without splenomegaly there are four that were confirmed by autopsy; one of Osler's, one of R. C. Cabot's, one of Christian's of the Peter Bent Brigham Hospital, and one of Herringham's. Thus the case is by exclusion one of erythremia without evident splenomegaly.

830 DECK STREET.

PATHOLOGICAL CONDITIONS OF THE ORGANS OF REPRODUCTION IN THE FEMALE CAUSING AND SIMULATING GASTROENTERIC DISTURBANCE.

By JOSEPH H. KATZ, M.D.

BROOKLYN, N. Y.

THE female sex, as a whole, is more subject to digestive disorders than the male sex. One of my old teachers used to define woman as "A creature of figure eight, having hair on one end, leucorrhea and constipation at the other end." This, as well as other like definitions, may sound humorous, yet it is true as far as digestive disturbances are concerned. Considering their make-up, mode of living, and dress, and the physiological processes—menstruation, starting at an early age, throwing the nervous balance into disharmony for a time, altering the internal secretions, repeated monthly,

giving rise to congestions in nearly all vital organs, then matrimony, even without pregnancies, causing changes and slight alteration, for a time, in the workings of the female physiologic machinery, then pregnancies, lactation and again monthly menstruation, not even considering the pathological conditions that may arrive from all these phenomena—one finds enough, even though physiological, to cause any disturbance in a human machinery. By adding the pathological factors to the normal physiological female mechanism it is easy to comprehend the harm done to other organs and systems of the human being and how they interfere with its mechanism and normal physiological work.

In speaking of pathological conditions in females, I would like to include not strictly pathologic conditions in the organs but aberration from the physiological on the part of the women:

1. *Abnormal or unnatural coitus*; due to fear of conception. Most of the cases of nausea, sometimes vomiting, headache, constipation or sometimes diarrhea, slight pain in lower abdomen, sometimes simulating even appendicitis, where no real organic disturbance in the digestive tract can be traced, are due to the above mentioned cause which, by creating a nervous disturbance, leads to improper circulation and digestive rearrangement.

2. *Abortion* or sudden interference with pregnancy, where physiological processes have begun to adjust themselves after sudden evacuation of the uterus, which has to undergo involution, changing again from a nearly compensated, so to speak, settled physiological state into a normal physiological state, throwing the balanced human system again into discord, and causing—not thinking of the pathology that may sometimes arrive as infection, etc.—gastric derangement sometimes requiring a long period of time to relieve, the patient often remaining a dyspeptic for life.

3. *Retroversion or Retroflexion uteri*. The constant lodging of the mass and pressing against the lower end of large bowel, preventing its easy evacuation, causing the lower bowel at first to do more work—peristaltic action to drive its contents against a force put on it by the mass and later producing an overworked dilated lower bowel unable to evacuate, sending reflexes to the whole digestive tract and thus disorganizing its system.

4. *Partly involuted uterus*, flabby, boggy, large, besides disturbing the normal internal secretions and adjacent organs, has the same effect as retroversion.

5. *Prolapsus uteri*, which manifest its effect first by pressing upon lower bowel; secondly, by being lowered from its original normal location, leaving a vacant space at times causing sinking of all abdominal contents, sometimes a general ptosis, thus disturbing the smooth straight outline of the intestines, and converting it into twists and kinks, preventing its easy mechanism and causing at times a severe pathologic condition in the whole tract.

6. *Tears at perineum*, disturb the natural abdominal strength, and weaken the vis-a-fronte in the natural forces of abdomen, so far as digestive work is concerned.

7. *Tumors of uterus* or adnexa are too well known to be discussed.

8. *Inflammations of uterus and adnexa* are often

met with, and their effects on gastrointestinal tract are well understood.

The last condition I am going to speak about seems to me very important and yet most neglected from the standpoint of the gastroenterologist, namely:

9. *Erosions and inflammations of the cervix*, may simulate nearly every gastroenteric disturbance possible, and in order to bring my point home, I shall better emphasize it by illustrating with several cases that recently came under my care and observation for various digestive disturbances and who were relieved or cured by treating the cervical pathology.

CASE I.—Mrs. X, age 32 (looks much older), married, Russian, referred to me at the gastroenteric clinic of the New York Post-Graduate Hospital by Dr. Woloshin of the medical clinic. Previous history negative. Began to menstruate at 15, married at 22, gave birth to six children, first child taken by instruments, the rest normal deliveries; perineal lacerations, repaired with good results. Present complaint dates back to last childbirth about four years ago. Pain in epigastric region nearly constant, relieved by rest and heat, aggravated by food. Constipated, at times nauseous, pyrosis relieved by drink and sodii bicarbonate; sometimes pain at night; no headaches, but weak and emaciated. Has been treated for ulcer and appendicitis with no relief. On further questioning the following points were brought out: that the pain sometimes radiates downward to pubis and even to inside vagina, painful coitus, very painful menstruation, rest and hot applications to lower abdomen relieves the condition. Vaginal examination revealed the following: lacerated, eroded cervix; cervix large, boggy, circumference double the size of a normal average cervix; right adnexa rather tender to pressure, although not palpable. Under cervical treatment the condition subsided and gastric disturbances all went.

CASE II.—Mrs. G, 46, Russian, widow. Menses normal, gave birth to five children, one miscarriage at six weeks' gestation. Present complaint dates back about four months, starting with a cold and pain in epigastrium; advised by a physician to stay in bed for a few weeks. She followed instructions, but condition became worse; pain in epigastrium and lower abdomen was very severe; relieved by rest, food and sodii bicarbonate. Belching; sour regurgitation. Slight pain radiating from vaginal vault to rectum. On first casual examination, patient being in very painful state, I made a tentative diagnosis of ulcer. Put patient to bed, advised frequent, small, nonirritating liquid food, prescribed antispasmodics, hot application to lower abdomen. In one week patient improved so that she asked permission to be allowed out of bed; when out of bed the pain returned only in the lower abdomen. I was called in again and made a vaginal examination, finding in exposing the cervix a pussy discharge from an eroded area. The cervix was swollen and boggy. Under cervical treatment the pain and other symptoms cleared up.

CASE III.—Mrs. F. Born in United States, aged 28, married. Gave birth to one child about two years ago; since then complains of constipation, pain and tenderness at McBurney's point. Operation for appendicitis was advised. I was consulted, and on examining her, although she was complaining at the time of pain, I could not elicit local deep tenderness at McBurney's, there was no rigidity of recti muscles; at no time did she have any elevation of temperature. I made a vaginal examination, finding a deep lacerated and eroded cervix. Advised repair and treatment of cervical pathology, which was done, relieving all the symptoms.

Conclusions.—A vaginal examination should be made in all female, married patients complaining of digestive disturbances, exploring the uterus and its adnexa, convincing oneself of its freedom from pathological conditions, before beginning treatment for the digestive complaints.

Medicolegal Notes.

Father's Failure to Provide Medical Treatment for Burned Child Not "Manslaughter."—The Florida Supreme Court, reversing a conviction imposing a penalty for manslaughter on an indictment charging that, by means of culpable neglect to support and provide for his minor daughter, she was unlawfully killed, holds that the failure or refusal of a father to provide medical attention for his child, who was accidentally burned by falling into a fire, from which burns the child subsequently died, does not make the father guilty of the crime of manslaughter, defined by the Florida statute to be "the killing of a human being by the act, procurement or culpable negligence of another." In a concurring opinion Chief Justice Browne says that the reasoning upon which the State's case rested was this: The child was badly injured; it did not have medical attention for three weeks; after that it was in the care of a physician for two weeks before it died; if the father (who was a believer in Divine healing) had called a physician it would have recovered; therefore the refusal of the father to call a physician caused the child's death. The fallacy of this, Chief Justice Browne says, is that it was not proven, and was not capable of being proven that if the child had had medical attention it would have recovered. And that must always be the fallacy in an attempt to attach the guilt of manslaughter to a father for failing to call a physician whenever his child is sick, if it subsequently dies. In a dissenting opinion, Mr. Justice West discusses various cases relating to the point.—*Bradley v. State* (Fla.) 84 So. 677.

Hypothetical Question Omitting X-Ray Result Errorneous in Malpractice Action.—In a malpractice case a new trial was granted after a verdict for the plaintiff, for error in permitting a medical expert witness for the plaintiff to answer a certain hypothetical question. The evidence showed that the defendant had charge of the plaintiff from the time of the injury, a fracture of one or more of the pelvic bones, causing the head of the right femur to be driven in. Soon after the accident, the defendant took two x-ray pictures of the region of the pelvis and used these pictures in making his diagnosis. It was admitted that these did not show a fracture, and it was clear that they did not reproduce the parts of the pelvis where the fracture or fractures occurred. There were x-ray pictures in evidence taken by others after the defendant ceased his treatment, and these plainly showed a fracture. The hypothetical question, with much confused detail, gave a history of the case and of the treatment, assumed that a fracture existed, and then, "assuming all of these things to be true," asked "whether or not, in your opinion, the examination and treatment employed by the attending physician was in keeping with proper practice." The question assumed that the defendant took x-ray pictures as above mentioned and that he reported to the plaintiff that there were no bones broken, but the pictures were not produced and the question did not assume or call further attention to the result of the x-ray pictures taken by the defendant. This was held error for the reason that the pertinent inquiry was not whether or not there was a fracture in fact, but whether, on all the data considered by the defendant in his diagnosis, his conclusion that there was no fracture was arrived at in the exercise of due care; that negligence in a malpractice case is to be determined by reference to pertinent facts existing and of which the physician knew or should have known in the exercise of due care at the time he acted, and that the expert witness should have been placed in the position the defendant was in when making his diagnosis, and should then have been permitted to give the jury his opinion as to whether the defendant used due care. A hypothetical question must embody substantially all the undisputed facts relating to the subject upon which the opinion of the witness is asked. This question did not do so. The witness was asked the broad question whether the defendant's examination and treatment were in keeping with proper practice. He could not answer that question with justice to the defendant without considering the x-ray pictures.—*Harju v. Allen*, Minnesota Supreme Court, 177 N. W. 1015.

MEDICAL RECORD.

New York, February 5, 1921.

THE ATYPICAL FORMS OF AORTIC INSUFFICIENCY AND MITRAL STENOSIS.

It might be assumed from reading most textbooks that the differential diagnosis of the various valvular lesions can be made without much difficulty. The presence of a murmur over a distinctly limited focus, its appearance at a specific time in the cardiac revolution, its intensity, tone, manner of propagation in a given direction, the presence of a rolling sound, etc., forming a symptomatic ensemble which might appear to possess a pathognomonic value. Now, such a schematic grouping, which is absolutely necessary for the needs of elementary teaching, will lead to serious mistakes when resorted to for clinical application, and Ribiene has recently called attention to this fact and insists on the atypical forms—larvate and otherwise—of certain valvular cardiopathies, foremost among which he places aortic insufficiency and mitral stenosis.

The classic signs of aortic insufficiency are a diastolic murmur over the third right costal cartilage which extends along the right edge of the sternum. In type it is soft and aspirating, present during all or part of the diastole, while the pulse is bounding, depressible. Now, this diastolic murmur at the base, which Laubry and others regard as of special value no matter where its maximum focus exists in the precardiac region, may be seated in proximity to the left third costal cartilage, at the apex of the heart, tip of the sternum, left axilla, or even in the left interscapulo-vertebral space. Its propagation is also very variable, since it may extend along the left border of the sternum toward the apex of the heart or toward the second or third left intercostal space. It is often detectable outside the limits of its usual focus quite far from the base toward the lower part of sternum, a little above the xiphoid appendix, less frequently towards the cardiac apex. In marked insufficiency the murmur replaces the snap of the aortic valves and fills the diastolic silence, but there are cases in which the valvular snap can be clearly heard and it is only afterwards and instantaneously that a very brief murmur can be detected and must be searched for. Finally, aortic insufficiency without

a murmur, on which Bard and his school have insisted, is now generally accepted. The disappearance of the murmur does not seem to be influenced by age, sex, modality, or cause of the cardiopathy. Bard attributes it to the progress of the arrhythmia which lessens or causes the disappearance of all murmurs, as well as complete arrhythmia and the coexistence of other valvular lesions, aortic or mitral.

During the phase of formation of the lesion the absence of the murmur is very important. Bard maintains that it is wanting especially in insufficiency of arterial origin where the lesions develop slowly, while its absence is the exception in rheumatismal valvular endocarditis. However, Ribiene recalls the fact that in rheumatism certain signs may lead one to foresee the appearance of the lesion. Durozier's double crural murmur, muffling of the second aortic sound, its parchment-like character often preceding the diastolic murmur, are characteristic of the valvular lesion.

The diastolic murmur is often wanting in the functional aortic insufficiency of high blood-pressure; it only appears at the time when the myocardium is giving way, when the heart has become somewhat dilated and disappears after a few days of rest in bed. It is very unusual that aortic insufficiency goes through its entire evolution without a murmur, but this important sign may nevertheless be wanting for a long time. The larvate forms of mitral stenosis may easily escape notice by an inattentive observer and unfortunate mistakes in diagnosis may ensue.

The tuberculous and chlorotic forms of mitral stenosis are known. In the former, the hypertension in the lesser circulation engenders pulmonary phenomena which cause one to suspect a commencing tuberculosis. These patients have dyspnea and cough, are subject to repeated bronchitis and hemoptysis and if the temperature goes up or the general health declines, a diagnosis of tuberculosis may be made when a more attentive examination would have revealed mitral stenosis. Mitral stenosis may also simulate chlorosis, usually in pale young females. There is oppression which is due to the existing anemia, amenorrhea, or dysmenorrhea, epistaxis, gastric disturbances and occasionally a very manifest neuropathic state. These symptoms indicate the real trouble, which is a mitral stenosis, and mistakes in diagnosis must be carefully avoided. It is, in fact, uncommon to find all the signs attributed to this lesion in a patient, because were this so it would be inexcusable to overlook it. A fruitless search may be made for presystolic increase, diastolic rolling and doubling of the second sound, because many mitral stenoses remain perfectly silent. Iluchard made nine autopsies on subjects with this lesion in which during life there was nothing detected by auscultation.

The occult character of certain instances of aortic insufficiency is very striking, as well as of some cases of mitral stenosis. Therefore, auscultation alone cannot always solve the problem of diagnosis and all means at our disposal should be

resorted to, including orthodiagraphy. It should also be recalled that the variability of the signs of valvular cardiopathies is frequently related to the phase of the evolution of the lesions.

THE RARER LOCALIZATIONS OF ARTICULAR AND MUSCULAR RHEUMATISM.

It would appear that the number of localizations of muscular rheumatism has considerably increased since the war, at least such is the opinion of competent observers. This fact may be attributed to prolonged duty in the trenches, to long and forced marches, and to thermic and mechanical traumata to which soldiers are particularly exposed. First of all, a special place should be given to rheumatismal affections of the muscles and tendons of the lower limbs, but this is so well known that it requires no comment.

On the other hand, many officers suffer from rheumatism of the muscles of the thorax, which is too frequently mistaken for a symptom of pleurisy. As differential characters may be mentioned, the absence of friction sounds and cough and a peculiar sensibility of the intercostal muscles, especially in the upper intercostal spaces with, occasionally, an inflammatory edema of the skin, with extreme sensibility over the point of junction of the osseous parts of the second and third ribs and their cartilaginous portions. In this respect a case of rheumatism of the thorax has been recently recorded by Janowski, of Warsaw, in which it was very difficult to come to a diagnosis, and this observer points out that the sensibility of the muscles in these cases results in a marked decrease of the respiratory murmur which may be the cause of mistaken appreciation of the case. Hence the necessity of very careful palpation of the thorax in patients complaining of such localized pain before making the usual diagnosis of pleurisy, or even, as has happened in not a few cases, of pneumonia.

There are three rare localizations of articular rheumatism to which attention should be directed. The first is that of rheumatism of the sacroiliac synarthrosis, which appears to be becoming very prevalent. The diagnosis of sciatica, or even osteomyelitis of the iliac bone, has been made, so severe have been the painful phenomena. Next in order comes rheumatism of the intervertebral articulations. Janowski reports an interesting example of this condition in which the four vertebrae of the neck were involved and in which the pain was so intense that a basal meningitis might easily have been diagnosed if care had not been taken. In other instances, the rheumatic process becomes localized in the dorsal vertebrae and may closely simulate Pott's disease, vertebral syphilis or even cancer of the esophagus. Finally, there is a localization of rheumatism at the junction of the ribs with the spine, usually in the four or five last ones. In these cases again pleurisy may be suspected or pyelitis or paranephritis may be diagnosed. But the sensibility is singularly increased by forced movements of the trunk while the pelvis is immobilized, while careful

palpation will locate the maximum point of pain over the points referred to. Palpation of the neighboring vertebrae may occasionally be painful.

In all these rather uncommon manifestations of rheumatism the test by salicylate medication is sometimes the best means of clearing up a difficult diagnosis.

KERATIN DERIVATIVES FOR THE STIMULATION OF HAIR GROWTH.

In the *Wiener klinische Wochenschrift* for August 5, 1920, xxxiii, 32, Fuhs gives a full account of this preparation and its effects on the organism. Early in the present year Professor Zuntz, the well-known biochemist, announced the discovery of a specific nutriment for the hair which has become of great interest to the dermatologist. It has long been known that the growth of hair in wild animals could be improved by the phosphorus and lime of the salt licks. Zuntz obtained the idea that certain constituents of horn with high sulphur and cystin content might exert a nutrient action in disturbed hair growth. First he gave a certain amount of hydrolyzed keratin *per diem*—1 to 1½ gms.

Blaschko, the dermatologist, then began the use of a chemically pure horn hydrolysate in the clinic and announced good results in the various cases of alopecia. In order to obtain a quantitative test to control the statements of patients a certain area of the scalp was closely clipped and the clippings weighed on a delicate balance. The hydrolysate was then given for a month and the scale then showed a double amount of clippings. Similar experiments with wool sheep showed a gain of over one-third in the yield of wool. Professor Riehl, another dermatologist, then tried the preparation in certain cases of alopecia, for a period up to two months. The cases comprised alopecia areata and symptomatica and the seborrheic form as well as normal scalps. But little improvement was noted in the first named form and the same was true of the symptomatic and seborrheic forms, while in the normal scalps there was no increase in hair production, or in the length or breadth of the individual hairs.

It is difficult to understand why the remarkable results obtained by Zuntz and Blaschko could not be corroborated. The best that can be said is that the remedy produced no bad collateral effects and it may be possible that the scanty material in some of the forms of alopecia was insufficient for a fair test. The results reported by Zuntz for sheep have not been controverted and would seem to be beyond doubt. They are at least encouraging for a further trial in the human subject. Curiously, although no attention was at first paid to nail growth in general, from the use of the remedy, one of the subjects while under the influence of the hydrolysate presented an increase in the mass of one or more nails. This suggested measuring the nail growth by making a file mark at the border of the lunula, which was done in 17 of the patients. Not one, however, showed any accelerated growth rate or increased production of nail substance.

EPIDEMIC ENCEPHALITIS.

ONE of the most complete short accounts of this affection which has yet appeared in literature is to be found in the *Anales de la Facultad de Medicina* of Montevideo, July-August, 1920, v, 7-8. The author is Dr. Ricaldoni, and the deductions are made from extensive personal experience controlled by the writings of authorities in other countries. At the time of writing the disease was epidemic in the Uruguayan capital. There is evidence that gripe has preceded some cases, while in others a preceding gripe may have conferred immunity. The extreme variety of symptoms and the number of types are readily explained by the diverse localization. In addition to focal symptoms there are radiated symptoms; but the remote lesions themselves may be due to unusual independent localization. The former the author terms derived symptoms, the latter aberrant symptoms. There are also frank and abortive forms, typical and masked forms.

Disturbance of the motility of the eye is responsible for a group of symptoms. There is also a lowered muscular tonus. Ptosis was once thought to belong under the dyskineses but actually, at least in many cases, it results from muscular hypotonia. Dissociation in the innervation of the eye amounts in some cases to complete anarchy. The two eyes act individually and independently, much as when a subject is being anesthetized with chloroform or ether. There is a similar dissociation in muscular tonus. Spasticity and hypotonia may be seen side by side. Muscular rigidity is seen in much variety and may be total, simulating or causing the Parkinsonian syndrome. The author has little to say of the pareses. The toxo-infectious manifestations are very few, pulmonary complications being sometimes seen. Fever seems constant and universal.

Under irradiated, derived and aberrant types the author enumerates forms of delirium, intense meningeal reactions, hemiplegias of several types, facial paralyses, trismus, paraplegias, retention of urine, bulbar symptoms, and various algias. The course is prolonged, convalescence seeming interminable. Death is preceded by hyperthermia, and followed at times by sweating (postmortem sweating). Of unique manifestations the author saw a subject with chronic paralysis agitans improve notably after an attack of encephalitis. The mortality in Uruguay has been lower than in some localities—19 to 20 per cent.

CAUSES OF DEATH OF THE FRENCH KINGS.

IN the erudite little book on the causes of death of the English kings, the learned author, it will be recalled, utterly ignores the doctrine of the modern origin of syphilis and makes the latter the actual or contributory cause of death of a number of the monarchs who reigned before the discovery of America. A propos of this a new edition of Witkowski's "Comment moururent les Rois de France," has recently been issued, and a notice of it appears in *Le Progrès Médical* for Nov. 13, 1920, xlviii, 46. This author has the merit of proving or making highly probable that the deaths of the monarchs

were due chiefly to the most banal affections such as cancer, tuberculosis, and pneumonia. The tendency of the older biographers of this type was to accuse either poison or some effect of immoral life. Witkowski has devoted forty years to medical history and in consequence has become severely critical, and he has eliminated many conclusions from specious reasoning. Charlemagne seems to have died of pneumonia, while Louis VII and Philippe VI succumbed to the results of venereal abuses, and François I died of syphilis outright. Louis X is said plausibly to have died from the effects of a draught of ice water. But it is possible to throw doubt on such diagnoses because the symptoms were not recorded by men of professional training. Witkowski has sought to assemble the evidence of qualified medical men, results of autopsies, and the character of the treatment given. In any case the subject is one fit only for passing the spare time of those of scholarly tastes, and the conclusions should be accepted at their true value, which is very slight.

INTESTINAL PERFORATION AND CHILD TYPHOID.

A YOUNG child usually escapes the fatal ending in typhoid fever because of its relative immunity from intestinal lesions, but when the latter do develop they give a grave prognosis. In other words only about 1 per cent. of children develop these complications, but the mortality is two patients out of three. Gioseffi contributes a brief clinical article on this subject in *La Riforma Medica*, 1920, xxxvi, 42. The case observed by him occurred in a girl of 14 admitted to the clinic with malaise and vomiting. She had had nosebleed and the pulse was dicrotic. After several days there was tenderness in the right inferior quadrant of the abdomen. The seroreaction was then negative for typhoid. The spleen was enlarged a little but a roseola had not appeared. The abdominal symptoms increased and peritonitis was evidently beginning. The blood tests had not been completed when the indication for operation became urgent, as perforation was believed to have occurred. Laparotomy gave exit to pus and gas. The same day there was a positive Widal, rather weak, and Ebert's bacillus was also found in pure culture. The patient recovered. The case is of interest from the simulation of typhoid appendicitis. The author has seen another case in a child of 6 in which the perforating ulcer was seated in a Meckel's diverticulum. In this young subject the typhoid syndrome was not present, the only symptoms being meteorism and semicollapse attributed to endocarditis. Hence no operation had been performed.

News of the Week.

House Leaders Approve Program for Veterans' Hospitals.—Republican leaders in the House of Representatives have given their approval of a program which calls for the construction of five hospitals for war veterans suffering from mental and nervous disorders and tuberculosis. A bill appropriating \$13,000,000 for such hospitals will be introduced. The estimated cost of the hospitals is \$2,500,000 each, and the remainder of

the fund will be used to convert buildings in the Government reservation at Walla Walla, Wash., and at Fort McKenzie, Wyo., into hospitals. Members of the Appropriations Committee have given assurance that they will report the bill favorably.

Committee Reports of Sheppard-Towner Bill.—In its report on the Sheppard-Towner Bill, which provides an appropriation of \$1,480,000 for safeguarding the health of mothers and babies, the House Commerce Committee classed this bill as emergency legislation and said there was practically no opposition to it. The committee finds that the maternal and infant mortality in the United States is not decreasing, statistics showing a 15 per cent. increase in deaths from child-birth between 1919 and 1920. The report states that in rural districts 80 per cent. of mothers receive no advice or trained care preceding the birth of children and that motherhood is safer in any of seventeen foreign countries than it is in the United States.

"Sleeping Sickness" in Sweden.—A cablegram from Copenhagen, under date of Jan. 29, reports that from Jan. 1 to 15 there were 203 cases of "sleeping sickness" in Sweden, 12 of which have terminated fatally.

Chicago Combats Epidemic Encephalitis.—According to Dr. C. St. Clair Drake, director of the State Health Bureau, lethargic encephalitis is prevalent in Illinois. Up to January 26, 33 cases have been reported in Chicago. A field physician from the State Board of Health has been assigned to study these cases in an effort to combat the spread of the malady.

English and French Birth Rates Rise.—According to the Registrar General's provisional returns for 1920, births per thousand of population in England and Wales were 25.44 and in London 26.3. Deaths were 12.4 per thousand in England and Wales and also in London. The infant mortality rate per thousand was 80 in England and Wales and 75 in London. The birth rate for 1920 is the highest for a decade and the highest ever recorded, while the death rate, as a whole, as well as the infant mortality rate, is the lowest ever recorded. In Paris during the last year 55,813 children were born, while there were only 43,000 deaths. There have not been as many births since 1901, when the number exceeded 56,000. During the war the births fell as low as 28,200 in 1916 and 30,400 in 1918. While the figures are not yet available for the entire country, the increased number of marriages in 1919 warrants the assumption that a similar increase in births may confidently be anticipated. In all the birth statistics the proportion of boys to girls is about seven to six in favor of the male sex.

Wants Federal Control and Pay for Physicians.—Ex-Mayor Heth of Kitchener, Ont., himself a doctor, in an address recently delivered at St. Catharines, urged the nationalization of the medical profession. He advocated placing doctors under Government salary and educating the public by a system of lectures on hygiene. He also declared that about 50 per cent. of the operations now being performed were unnecessary.

Asks Nobel Prize for American Red Cross.—

The Finnish Government has decided to recommend to the Nobel Prize Committee that the Nobel Peace Prize be made to the American Red Cross, on the ground of "its blessed activities materially relieved suffering in the war, served the purposes of humanity, and promoted mutual solidarity of the nations." During the past year the American Red Cross, as shown in a recent official report, spent \$780,000 in 57 large disasters in the United States. In these disasters 425 lives were lost, 2,700 persons were injured, and the property loss was \$11,250,000. Besides giving aid in domestic troubles, the Red Cross assisted sufferers in earthquakes in Italy and Mexico, extended aid to famine sufferers in China, and took part in relief work in Haiti during an epidemic.

Constitutional Amendment Eliminates Lunacy Commission.—The proposed constitutional amendment which would eliminate the New York State Lunacy Commission and provide instead for a commission on mental hygiene to inspect all institutions for the care of the insane, epileptics, idiots, feeble-minded and mentally defective was introduced into the Legislature on January 28. This measure passed the Legislature last year and if passed again this year will go to the people for their general approval at the general election next fall.

Bill to Assist Pension Fund.—A bill introduced into the New York State Legislature by Senator McCue provides for appropriations to meet any deficiency in the New York City Health Department Pension Fund.

Nurses Poisoned by Canned Spinach.—Twenty nurses and attachés of the Blodgett Hospital, Grand Rapids, Mich., partook of canned spinach at luncheon on Jan. 22, and all have shown signs of poisoning. As a result two of the nurses and one orderly are dead and several others, at the time of writing, were in a critical condition.

Two Additional Diseases Made Reportable.—The New York City Board of Health, at its meeting on Jan. 28, passed resolutions placing botulism and encephalitis lethargica on the list of reportable diseases.

Health Supervision an Aid to Industry.—The National Industrial Conference Board, with headquarters at 10 East Thirty-ninth Street, New York City, has just published the results of physical examinations of industrial workers in thirty-four plants, which go to show that these examinations have increased efficiency, diminished accidents, reduced absence, lowered the labor turnover, eliminated tuberculosis and other contagious diseases, brought about a better adaptation of the worker to the job, and a feeling among employees that their interests are being intelligently safeguarded. The study includes 410,106 workers, 237,183 men and 82,923 women. Little or no objection to the examination was shown on the part of the workers, the largest number of objections being 200 among 62,000 employees. Ten plants employing 155,000 workers had no refusals. Physical examinations were introduced into this group in 1910 but in twenty-three of the thirty-four plants they were not introduced until 1914 or later.

Serum Cures Dogs of Rabies.—A special cable-

gram to the New York *Herald* states that Professor A. Marie and Professor Remlinger of the Pasteur Institute announce that they have discovered a new serum which will cure dogs of rabies and render them immune to that infection thereafter. They express the belief that the new serum will be equally effective when applied to human beings.

Board of Regents Approves Army School for Nursing.—The Board of Regents of the State of New York, at a meeting held Jan. 1, 1921, formally registered the Army School of Nursing, under section 421 of Regents Rules, as an approved training school for nurses. The Army School of Nursing is conducted in connection with the Walter Reed Hospital, Washington, D. C., and the Letterman General Hospital, San Francisco. At present there are about 520 student nurses enrolled in the Army School of Nursing. In addition to the facilities afforded students in this school by army hospitals, arrangements have been made whereby they receive special instruction in affiliated civil hospitals and welfare institutions.

Fumes from Jersey Shore Minimized.—At a hearing held at the New York Academy of Medicine Jan. 29, at which Dr. Hermann M. Biggs, State Health Commissioner, presided, the acid fumes nuisance from New Jersey plants opposite Riverside Drive, Manhattan, was discussed. Dr. Theodore Horton, engineer of the State Department of Health, stated that his observations showed that the pollution of the atmosphere over the West Side of Manhattan has been lessened considerably as a result of installation of apparatus to control the fumes. This apparatus is said to result in a great diminution of the objectionable fumes though the system is not entirely satisfactory.

Nurse Buys Drugs on False Permit.—A woman, giving her name as Mary Smith, was recently held in \$500 bail in the West Side Court, Manhattan, charged with obtaining narcotics falsely by forging a physician's name. The prescription calling for twenty-four morphine tablets was written on correspondence paper, and the druggist's suspicions led him to telephone to the physician, who notified the narcotic detectives.

Dies at Ripe Old Age.—Mrs. Anne Lizea Philips Hastings died in West Chester, Pa., on January 29, in her 108th year. She was born in Framingham, Mass., in 1814.

Dr. Pearce Bailey of New York has been awarded a Distinguished Service Medal by the War Department for his services as Chief of the Division of Neuropsychiatry, Surgeon General's Office.

Dr. George Gray Ward, Jr., has removed his office to 48 East Fifty-second Street, and not West Fifty-second, as was printed in a previous notice.

Memorial to Sir Victor Horsley.—Friends and colleagues of the late Colonel Sir Victor Horsley have organized to take steps to commemorate his services to science and the British Empire by the foundation of lectureship or scholarship bearing his name. It is suggested that the most appropriate trustees would be the Senate of the University of London, and that if a scholarship should be finally decided upon, the subject should be left

widely open so as to secure the services of men distinguished in some department of public life who might consider it an honor to be the "Victor Horsley Lecturer" for the year. Sir Charles Ballance is chairman of the General Committee. Other officers are. *Honorary Treasurers*, Sir Frederick Mott and Dr. H. H. Tooth; *Honorary Secretaries*, Sir Arbuthnot Lane and Edward J. Domville. A considerable number of contributions to the fund have already been received. Subscriptions may be sent to any of the above-named officers or to the "Victor Horsley Memorial Account" Westminster and Park's Bank (Hanover Square Branch), London County.

Italian Society of Medical Radiology.—This organization announces that its third congress, held in Rome October 28-30, 1920, was highly successful. One hundred communications were presented and freely discussed, showing that great interest has been aroused in the medical aspects of radiology in Italy. Professor Ghilarducci presided at the meeting.

Semi-Centennial of American Public Health Association.—The fiftieth annual meeting of the American Public Health Association will be held in New York City in November, 1921. The date tentatively announced is November 14-18. The first organization meeting of the Association was held in New York City on April 18, 1872, and at that time Dr. Stephen Smith of New York City, who is now 99 years of age, was elected first president of the new organization. It is anticipated that his approaching centennial may be celebrated together with the semi-centennial of the Association.

The Brownsville and East New York Hospital.—A lecture by Prof. E. V. McCollum of the School of Hygiene and Public Health of Johns Hopkins University was delivered on January 29 at the Kings County Medical Society, Brooklyn, on the subject of "Nutrition." This was the first of a series of monthly lectures to be given under the auspices of the medical staff of the Brownsville and East New York Hospital, Brooklyn. The latter institution will open its doors for the reception of patients about March 1.

Obituary Notes.—**PROFESSOR WILLIAM THOMPSON SEDGWICK**, professor of biology and public health at the Massachusetts Institute of Technology, died suddenly at his home in Boston, on January 26, at the age of 65 years.

Dr. DAVID LUTHER HAZARD of Berwyn, Md., died at his home on January 22, at the age of 74 years.

Dr. JAMES H. BROWNFIELD, a graduate of Jefferson Medical College, in 1878, died at his home in Fairmont, W. Va., about January 20, at the age of 84 years. He served in the Union Army during the Civil War and was once Mayor of Fairmont.

Dr. EDWARD W. KELLOGG, the family physician of Mark Twain, Charles Dudley Warner, and Harriet Beecher Stowe, died at his home in Avon, near Hartford, Conn., on January 15, at the age of 80 years. He was a graduate of the Long Island College Hospital in 1867, a former president of the National Homeopathic Medical Society, and Civil War veteran. Early in his career Dr. Kellogg was a musician, and one of his compositions, "We Three Kings of Orient Are," is widely known.

Correspondence.

THE REAL CAUSE OF STAMMERING AND A LOGICAL TREATMENT.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In an article entitled "Stammering As It Really Is" in the MEDICAL RECORD for December 4, 1920, Ernest Tomkins has endeavored to reduce the confusion of personal opinions and theories now existing concerning stammering. Mr. Tomkins has cleared up several matters, yet the treatment suggested in his last paragraph seems to me as impracticable of application as it looks sound in theory; and the experiments which I performed upon a trephined stammerer and upon other stammerers at the Harvard University Psychological Laboratory disprove his assertion that breathing exercises should be omitted from treatment.*

I agree with Mr. Tomkins that the stammerer's mind should be kept off the impediment in his speech and that vocal gymnastics, although sometimes necessary before or after treatment should be omitted during treatment, as they necessarily focus the patient's mind on his stammering. It would seem, at a casual glance, that breathing exercises should be omitted for the same reason, but my experiments show that a proper breath before speaking removes the real cause of stammering, and that such a breath is highly beneficial.

My experiments demonstrated not only that stammering was accompanied by marked cerebral congestion and vasoconstriction, but that sudden cerebral congestion and vasoconstriction, however induced, brought on either cessation of speech or stammering in normal speakers as well as in stammerers. When cerebral congestion ceased, stammering ceased. The emotions which were accompanied by marked cerebral congestion and vasoconstriction are the same emotions that aggravate stammering. A sudden blast of a shrill whistle while a person is speaking will cause immediate stammering if the speaker is able to speak at all.

My experiments showed that recovery from cerebral congestion and vasoconstriction can be greatly hastened by appropriate breathing. Quick breathing or sniffing increased cerebral congestion; slow, moderately deep breathing, preceded by a second of relaxation, reduced this congestion in a few seconds. Although breathing exercises in themselves may do little if any good, and a quick breath before speaking may aggravate the stammering, my experiments proved conclusively that a slow, natural breath, taken while the patient is relaxed, reduces cerebral congestion and encourages normal speech.

As my experiments demonstrated, also, that the surplus energy which stammerers frequently put into their speech is accompanied by cerebral congestion, it is important that stammerers should be taught to speak without effort. It is useless merely to ask them to speak without effort, because the more they try to, the more their attention is focused on their stammering, and the worse they stammer. If they breathe as I have outlined, they will have little, if any, tendency to put surplus

energy into their speech, and, with a little help from a competent teacher, they will be able to learn how to speak easily in a very few lessons. The breath will soon automatically remind them to speak correctly, just as putting on a shoe automatically reminds one to lace it up and tie the lacing. Then the stammerer needs only to think how he takes the breath with which he is to speak (for the purpose of speaking more distinctly rather than of overcoming stammering), before he focuses his attention on what he is saying. It does not take long to convince the patient that he *cannot* stammer if he breathes properly before speaking and speaks without effort. He at once associates this breath with normal speech because it is normal speech; and this association keeps his mind off his stammering and enables him to speak to any person anywhere at any time under any conditions without hesitancy.

Under this treatment the patient can at once fit into the environment wherein he lives; public opinion and sentiment, which are hard to change, need not be altered; the patient need not undergo the mortification of writing his message on a pad of paper, of using a poorer word for the one he desired to speak, or of desisting altogether from speaking, as Mr. Tomkins advises. Such mortifications only increase the fear of stammering and aggravate the difficulty. The fear of speaking under certain conditions can be overcome only by speaking normally under those conditions, as the treatment I have suggested makes possible. To forbid a child to stammer on school property would increase the fear of stammering and be equivalent to forbidding him to speak on school property, a rule obviously impossible to enforce. Children should be taught in the earliest grades of every school how to breathe properly and how to speak without effort, and their teachers should be instructed not to hurry them or to subject them to unnecessary embarrassment. Teachers should make it a rule to talk sociably with stammering pupils before and after school and thus let these pupils see that their teachers are interested in them and that they can speak fluently to their teachers. Children who ridicule stammerers on school property should be severely reprimanded and, if such cruelty persists, be suspended from school.

Although stammering may cease in a very few months under the treatment I have outlined, recovery does not come until this normal speech has become more natural than stammering. If the stammerer does not think how he breathes for a year or so after stammering ceases, or until this correct breathing becomes automatic, he will gradually revert to his old trouble. As he will unconsciously breathe the old way every time he does not remember to breathe the new way, he must constantly be reminded by a patient teacher throughout this period to breathe slowly. He should go to this teacher two or three times a week at first, and once in two weeks or once a month for at least a year after stammering ceases. Because of the habit nature of stammering and of the emotion of stammering, recovery is slow, and many stammerers who lack the ability to stick to anything fall by the wayside. In almost every case recovery is *certain*, however, if the patient persists for a year

*Robbins, S. D.: *American Journal of Physiology*, April, 1919, May, 1920.

or two, and it is well worth this effort; I myself have entirely recovered from a severe case of stammering, so I *know*.

SAMUEL D. ROBBINS, A. M.,

Director, Boston Stammerers' Institute.

MECHANOTHERAPY: A TERMINOLOGICAL READJUSTMENT.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—For one who has this particular therapy at heart, it is somewhat distressing to observe how dim is the average practitioner's conception, not only of its proper terminology, but also as regards its scope—not to mention its actual application. Possibly the reason for this may be found in the step-motherly manner in which most medical schools treat this therapy, and the fact that the student is imbued there with an idea that, although the subject cannot conveniently be altogether ignored, it is a matter of course that his dignity can not possibly permit him to put actually a hand to it—at any rate, so far as massage and medical gymnastics are concerned. And yet, how infinitely more important, as a remedial agent, is not Mechanotherapy than, for instance, Electrotherapy! This relatively *nouveau riche* among therapeutics has still to make good a great deal of its boasted reputation, based to no mean extent upon the optimistic speculations of its Liebhabers and a very human weakness on the part of the public for spectacular display. Whereas the former, old already at the time of Hippocrates, has plodded its more laborious way down the centuries, humbly but honestly, at times abused, at times forgotten, or obscured by things possessing the more acute charm of novelty, only to emerge to-day triumphantly, not only holding its own, but more than that, as the war more than anything has revealed to us. If age, ancestry, and tradition go to make the aristocrat, I would suggest that a great many of the therapeutic measures now in vogue may well make their respectful courtesy to Mechanotherapy.

What then does the word Mechanotherapy imply? To most people it suggests the employment of mechanical contrivances in the treatment of disease. To many it means Zander apparatus and nothing else. And indeed when I look for the word in Stedman's Medical Dictionary I get: "treatment of diseases by means of apparatus or mechanical appliances of any kind." And I am inclined to think it natural enough in a country so great on mechanical contrivances as this. I turn to the French *Encyclopédie Universelle du XXe Siècle*, but get from bad to worse; I read: "—le traitement des maladies articulaires et musculaires (note its limited scope) par des instruments mécaniques"; and the Spanish *Enciclopedia Universal Ilustrada* echoes very much the same: "—metodo terapeutico, que consiste en la aplicacion de aparatos, etc." Desperately I address myself to Meyers (German) *Konversationslexikon* for comfort, only to be referred at once to "Heilgymnastik," under which heading I find the word inseparably connected with Zander apparatus. Fairly disgusted, I fall back on the Swedish "Nordisk Familjebok," the last word in encyclopedias

and the pride of every Swede, and find to my horror the German version translated word for word from it—or vice versa. And I begin to understand how mechanical is the way in which encyclopedias and dictionaries are made up. Evidently, for some strange reason, perhaps lack of interest, the word Mechanotherapy has more or less universally come to imply treatment by some constructed apparatus or engine.

But why—in the name of Galileo and Newton—limit the word "Mechanism" to mere machinery? One may as well limit Mathematics to Laundry bills or Geometry to Union Square. That the word is derived from the Greek "mekhane," usually translated "machine," does not justify any such limitation since it is so freely applied in its larger philosophical sense, when used in other connections. Even Dr. Stedman expands into the larger conception of the word when defining "Osteopathy," which he describes as "a treatment directed to the mechanical correction by means of manipulation." Now, Osteopathy and Chiropactic (I have never been quite able to make out where the first ends and the second begins) are, if anything at all, but forms of mechanical treatment, forming like more static Orthopedy, part of Mechanotherapy—provided of course that by Mechanotherapy we understand the treatment of pathological conditions by *mechanical* means as distinct from, say chemical or thermal or electrical.

As for Orthopedics, no one will seriously deny its mechanical nature. Its connection with surgery is after all but incidental, unless one has in mind "bloodless surgery," and the fact that occasionally it avails itself of surgery as an auxiliary, hardly justifies the term "orthopedic surgeon," particularly popular in this country and used to signify a person, may be a surgeon, who specializes in the mechanical treatment of deformities, thereby by no means limiting himself to the mere static pressure afforded by bandages, splints, plaster of Paris encasements, and other orthopedic paraphernalia, but who also, and naturally, freely employs the "dynamic" pressure of massage, as well as medical gymnastics. The fact that the orthopedic surgeon usually considers it beneath his dignity to apply the two latter kinds of mechanical treatment in person, may well make him less efficient in his craft, but does in no manner influence their close and natural affinity to the first mentioned (orthopedics) especially when the treatment of deformities is in question. Incidentally it follows that, while the orthopedic surgeon is a mechanotherapist to the extent of 90 per cent. (allowing 10 per cent. for surgery), a mechanotherapist who confines himself to the treatment of deformities only, that is, becomes an "orthopedic surgeon," is limiting to about 10 per cent. the full scope and curative resource of Mechanotherapy.

The terminological inexactitudes thus abroad in matters belonging to the realm of Mechanotherapy seem then mostly to have their root and origin in this one fundamental anomaly: the deliberate limitation of the word *mechanical* as appertaining exclusively to machinery. The moment we think of the word in its broader sense, such terms and phrases as "mechanical massage," "manipulative and mechanical stimulation," "massage and mechanotherapy," etc., become absurd.

As a remedy for this anomaly I venture upon the extravagance of proposing the coining of a new adjective, to relieve the overburdened *mechanical*, namely *machinal*.

By mechanical massage is evidently meant massage applied by means of some mechanical contrivance or machine, as for instance a vibrator (vibrations being a form of *tapotement*) or certain forms of Zander apparatus. By substituting *machinal* for mechanical, we have at once the desired differentiation from *manual* massage, without offending the mechanical nature and dignity of either. Likewise "*manipulative* and *machinal* stimulation" both, of course, being mechanical). And so on.

In a paper giving printed kinetic instructions and informations, issued from the office of a prominent New York neurologist, I read the other day that "a resistance movement is a movement in which one group of muscles opposes another." This is an excellent definition of a balance movement, but of course has no application to a resistance movement. Mix-ups of this kind, although unpleasant for the parties responsible for them, are pardonable enough, since the enormous field and extensive terminology of Mechanotherapy requires considerable special attention, not always possible for the general practitioner to give to it. But when coupled, as they sometimes are, with a certain superciliousness, suggestive of omniscience, they become amusing.

FRITHIOF NORBERG.

8 WEST ONE HUNDRED AND FIRST STREET.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, January 7, 1921.

The Insurance Bill and Medical Research.—The Insurance Bill has been in many respects a failure, or perhaps it would be more correct to say a comparative failure. As regards the prevention of sickness, it is safe to say that it has been a failure, although it was introduced "for the prevention of sickness." Neither has the German Act on which it was modeled prevented sickness. However, as it is obvious that the prevention of sickness is, at least, as difficult of accomplishment as the treatment of disease (most authorities will probably agree that it is more difficult), it is easy to comprehend why the Insurance Bill has not fulfilled expectations and prophecies in this direction. If and when Sir James Mackenzie has succeeded in a scheme to teach general practitioners how to diagnose early symptoms of disease and the general public have been taught to consult medical men as soon as early symptoms manifest themselves, then will preventive medicine be placed upon a proper basis. But it must be borne in mind that the teaching and practice of preventive medicine itself is in its early stages and until it has been thoroughly organized it is futile to expect too much of it. The claim that the Insurance Bill in its medical aspects is a failure and especially from the point of view of the medical man himself, is, at any rate, partially justified. It has been damned with faint praise, while at the same time it has been loudly execrated by some. One feature of

the bill has been, nevertheless, worthy of the highest praise, the work of its medical research committee is that to which reference is made. It is superfluous to state that medical research in this country is not in the healthy state it is in America. Or rather it may be said that funds are lacking to prosecute medical scientific investigations in the way they should be prosecuted. Our rich men do not seem to have the far seeing vision of the American plutocrats and to recognize that money spent freely for the encouragement of such research is the act of wisdom from every standpoint. Prosperity and contentment originate from good health, and sagely directed medical research paves the way to good health. Although there is nothing here to compare with the Rockefeller Institute, nor is money forthcoming for medical research in the streams that flow from the pockets of American millionaires, yet medical research in Great Britain is by no means stagnant. The Medical Research Committee of the National Health Insurance Commission did yeoman work during the war, largely inspired and helped by that wonderful man, Sir Robert Morant, whose genius and intellectual foresight were chiefly responsible for the formation of the Ministry of Health and whose untimely death was an almost irreparable loss to that body and to the country. It was his view that medical research should not be limited by coming under a ministry which was not nation wide, but confined to England and Wales, and by his advice the Medical Research Committee of the National Health Insurance Commission became the Medical Research Council under the aegis of the Privy Council of which Mr. Balfour, a man of vision and science himself, is Lord President. The first report of the Medical Research Council has just been issued. The report, which is excellently compiled, is a veritable mine of valuable information and will be referred to and quoted from in succeeding letters. Among the manifold subjects discussed are the clinical work of hospitals, investigations into industrial disease and fatigue, and researches on influenza, tubercle, infant welfare in all its phases, vitamins, medical problems involved in flying and radiotherapy. The question here as regards medical research is very different from that in America. Money is badly needed in Great Britain to carry on such work in a manner best calculated to be most productive of good results. This country has an unsurpassed tradition of medical scientific research, an unfailing supply of men and women, who are willing to toil faithfully and unsparingly for starvation pay. It therefore seems incumbent on the Government to increase largely the trifling sum of £125,000 which Parliament votes for the purpose of medical research. Unfortunately, unless the public can be made to understand the inestimable value of wisely directed medical research Parliament is not likely to open its purse-strings more widely. The masses control Parliament to a very large extent, because they have the voting power. They do not understand the uses of medical science, it cannot be directly computed in pounds, shillings and pence, and therefore they despise it. If they can be taught to comprehend, as the rich men of Amer-

ica sagaciously understand, that money expended for the purpose of medical research will be returned an hundred fold, instead of dealing in niggardly fashion with laboratory workers and medical scientific investigators of every description, they will be eagerly anxious to endow medical research most generously. The masses and the rich, too, must be so educated that they will give freely to the cause of medical science, recognizing the fact that it is for the good of the country and the individual.

The Fellowship of Medicine and the Post-Graduate Medical Association.—At a general council meeting of this body held on December 10, 1920, the following resolutions were adopted and referred to the newly appointed executive committee: (1) That the executive committee be requested to consider the advisability and practicability of appointing a general organizer of post-graduate medicine with full powers to take such action as he thinks fit in order to promote the facilities for post-graduate education in the United Kingdom for practitioners registered in this country and for visitors from Dominions and foreign countries. And that the Government be approached with a view to obtaining an annual grant. (2) That the executive committee be requested to report at an early date upon the possibility of providing a hospital solely for post-graduate study and the possibility of obtaining a grant in aid. (3) That it is desirable to obtain as early as possible suitable accommodation for post-graduates attending courses of instruction. If those responsible for the direction of the medical schools of London wish, and no doubt they do wish, to make of London the great European medical center, they must bestir themselves or they may find that Berlin or even Vienna will regain its old pride of place as a center of post-graduate medical teaching. Too great insistence cannot be placed on the point that London possesses all the opportunities and facilities for post-graduate medical teaching and for Americans in particular. But these facilities must be organized and opportunities put to the best use. A laissez-faire policy will not do at the present juncture. Every effort must be made to attract post-graduate medical students, and to provide the best means of instruction, clinical and otherwise, and to make them comfortable and at home when they come. The establishment of an American hospital and club is the first step in the right direction, and the provision of a hospital solely for post-graduate study is certainly another forward step. It is to be hoped that both these schemes may come to fruition quickly.

The Treatment of Oral Sepsis in Great Britain and America.—Dental infection is frequent in Great Britain and in America and consequently the question of its treatment is important in both countries. Probably defective teeth are more often seen in the former country, due to the fact that more care is taken of the teeth in America. In connection with oral sepsis Dr. W. Bertram Watson contributed to the *Lancet*, January 1, last, an article on oral sepsis, in which, after pointing out that dental infection in Great Britain and America is one of the most widely discussed prob-

lems of the day went on to draw unfavorable comparisons as to the knowledge of dental disease and the condition of dental radiography in this country and the United States. He was greatly impressed during a recent visit to your side of the Atlantic, by the high standard to which this branch of medical science had attained and deplored the lack of progress made in this direction in his own country. In the next number of the *Lancet* Dr. Stanley Colyer, one of the leading dental surgeons here, took up the cudgels in defence of dental surgery. In his opinion since the great stir made by that pioneer, the Englishman, Dr. William Hunter, in 1898, the subject was earnestly and energetically taken up by doctors and dentists and is still being actively carried on. He allows, however, that American doctors have recently taken up the matter with characteristic vigor and thoroughness. Dr. Colyer further pointed out that dental radiography is by no means at a standstill in Great Britain and adduced several facts in support of this statement. It really seems that in his article Dr. Watson was casting reflections on the doctor's neglect of oral sepsis rather than upon the dentist's want of knowledge and progress in the treatment of oral sepsis and lack of appreciation of the value of radiography in its diagnosis. It is true that William Hunter was one of the first, if not actually the first, to draw attention to the evil influence on the general health exercised by infected teeth and gums. It is equally true that pyorrhea alveolaris was first diagnosed by the American, Riggs. Dentistry in this country has made great strides in the past few years and more particularly since the war, and although there is a scarcity of dentists, some remarkably good dental work is being done. There are, however, in this country, and doubtless in America, many prominent medical authorities who hold that an exaggerated importance is now attached to dental infection and that wholesale extraction of teeth is, at any rate, sometimes done when more conservative measures would answer the purpose better.

A Venerable Journal.—The *Medical Press and Circular* has reached the very respectable age of eighty-two years, this being exceeded in Great Britain only by the *Lancet*, which will soon be one hundred years old. In America, if my memory serves me right, the *Boston Medical and Surgical Journal* is even older than the *Lancet*, while the *MEDICAL RECORD* is of a grave and serious middle age. It is also interesting to note that since the transference of the *Medical Press and Circular* from Dublin to London in 1866 its management has been in the hands of Mr. Albert Alfred Tindall. Mr. Tindall is eighty years of age and still "going strong," and thus has been at the helm for fifty-four years, a record in journalism of whatever description.

The New Year Honors.—The New Year Honors List as it affects medicine is commendably and unusually short, and as mentioned in a former letter is unique in one respect in that for the first time medical journalism is recognized. Among the other Knighthoods awarded is that of Sir Edward C. Bigger, M.D., Crown representative on the General Medical Council, and late Medical

Commissioner to the Local Government Board, Ireland, and of Mr. Charles Ryall, F. R. C. S., senior surgeon to the Cancer and Bolingbroke hospitals. In the Colonial office list of honors appears the name of Dr. Alexander Jarvie Hood, senior physician to the Prince of Wales's Military Hospital, Randwick, New South Wales, who is given a knighthood. As the honors bestowed upon the editors of the *Lancet* and *British Medical Journal* may be justly regarded in the light of a tribute to medical journalism as much as to the abilities and personal qualities of the recipients, it will not be out of place to give a short sketch of their careers. Sir Squire Sprigge is the eldest son of the late Dr. Squire Sprigge, who was an able and greatly liked country practitioner of Norfolk, an East coast county of England. He was educated at Uppingham, one of the famous schools of England and at Caius College, Cambridge. He completed his medical education at St. George's Hospital, London, graduating in arts at Cambridge and taking the Cambridge degree in medicine. He also took the membership of the College of Surgeons of England. After holding various literary and professional posts, in 1893, he became associated with the *Lancet*, being appointed assistant editor in 1895 and editor in 1908, a position he still occupies. From 1910 to 1913 he was chairman of the Society of Authors, and he has himself written several works dealing with medical history and education, a volume of short stories entitled "Odd Issues," and an ingeniously conceived and amusing novel, "An Industrious Chevalier," which enjoyed a considerable vogue some fifteen years ago. Sir Squire Sprigge both from the point of view of professional and exact knowledge and of his literary attainments is well fitted for the post of medical editor. He has not only kept up the *Lancet* to the high standard set up by Thomas Wakley, its founder and first editor, but has moved with the times in the traditional somewhat conservative English way and has, moreover, impressed upon it his own individuality.

Dr. Dawson Williams, the editor of the *British Medical Journal*, when he entered medical journalism, enjoyed a greater clinical position than any other medical journalist. Neither Ernest Hart, whose assistant editor he became, nor the Wakleys of the *Lancet* had any thing like his scientific equipment. A gold medallist in medicine at the University of London and Fellow of University College, he was assistant physician to the East London Hospital for Children and the author of many papers, showing him to be in the van of the new medicine following upon the discoveries of Lister and the bacteriological work of Pasteur. With such a dossier Dr. Dawson Williams had no intention of making journalism his career. He came in under terms with which we are now so familiar, a "half-time man," but, as was inevitable, he soon found that as the conduct of the *British Medical Journal* fell more and more into his hands it became more and more impossible for him to attend to practice, and the inverse of this proposition, of course, is true. To the great benefit of medical journalism he elected to devote all his time to this, succeeding Ernest Hart in the

editorial chair early in 1898. As further evidence of Sir Dawson Williams's ideal that medicine should be international, it may be mentioned that he is treasurer of the International Medical Press, a body whose sessions before the war were held in conjunction with the meetings of International Medical Congresses and whose activities will no doubt be resumed when normal international relations are restored.

1. The Clinical Recognition of the Various Types of Paroxysmal Rapid Heart Action.—Samuel A. Levine holds that it is possible to distinguish the various types of paroxysmal rapid heart action (paroxysmal auricular tachycardia, paroxysmal auricular fibrillation and paroxysmal auricular flutter) one from each other and from normal acceleration by the simple means that all physicians have with them at the bedside in the majority of instances. The points involved in the differential diagnosis are discussed and the importance of vagal stimulation as a life-saving measure in rare instances is emphasized. The proper treatment of the various types of paroxysms will depend on the correct differentiation of the abnormal mechanism.

4. Gynecological Backache.—E. A. Bullard studied a series of 721 cases of backache at the Woman's Hospital, New York City, eighty-five per cent. of which were cured by an appropriate operation. About fifteen per cent. of this series, presenting one or more common gynecological causes of backache, were not relieved of the backache by anatomically satisfactory operations. Probably much more than fifteen per cent. of the backache in females is not gynecological. This series suggests that fifteen or twenty per cent. of all women with retroversion, prolapse, pelvic inflammations, obstetrical lacerations, or pelvic tumors, do not have backache. Closer cooperation with the orthopedist, the internist and the neurologist should enable gynecologists better to diagnose and treat backache in women.

8. Tabes Mesenterica Following Influenza.—Ralph J. Melman reports one case in a boy seven years of age, who made an uneventful recovery following operation under spinal analgesia. The following points are emphasized in connection with this history: 1. Severe pleuritic pain on the eighth day of the disease, which was thought to be referred from the abdominal cavity, possibly due to the fact that this complication commenced in that part of the peritoneum, in proximity to the diaphragm. 2. The peculiar temperature curve being at its highest between 11 A. M. and 3 P. M. 3. The importance of the von Pirquet test in conjunction with other phenomena in puzzling cases in children. 4. The importance of early surgical intervention in this disease, and not resort to watchful waiting until the glands

break down and have tuberculous meningitis as a possible complication. 5. It is interesting to note that in a proportion of cases of so-called potbelly, due to rickets, where distention persists, one may have as a complication a chronic tabes mesenterica.

2. Synergistic Colonic Analgesia.—James T. Gwathmey states the physiological fundamentals of colonic analgesia as follows: 1. It is necessary to give at one time the total amount, as determined by age, weight, and the general condition of the patient, in order to establish the ether tension in the blood, which is necessary to produce anesthesia. It is a fallacy to assume that the total amount given to a patient is immediately utilized. If this were so, there would be shock and gradual recovery with every oil-ether administration. As the plane of anesthesia is constant, it is now definitely established that the patient absorbs two ounces of ether an hour—a smaller amount than by any other method in common use. 2. After administering the oil-ether mixture, it is impossible to withdraw the oil and leave the ether, or to withdraw the ether and leave the oil. Every molecule of ether is bound to a molecule of oil, and this union is broken only when vaporization occurs. In no other way can they be separated. When anesthesia is established, it is automatically maintained by the ether separating from the oil according to certain inflexible physical laws. The amount of this vaporization never varies. Therefore it is impossible to have deep anesthesia at one time and a light anesthesia at another, unless the anesthesia is deepened by rebreathing or lightened by an airway tube. Thus the administration is as definitely under the control of the anesthetist at all times as if he were giving it by an inhalation method. While the total amount of the mixture is within the body, the patient is as safe from an overdose as if it were in a container outside the body. The patient under oil-ether colonic anesthesia inhales a warm, moist vapor at all times. When the ether is taken up by the small blood vessels surrounding the colon it is carried thence through the liver by the greater circulation and on to the heart; from there it is pumped into the lungs. By the time the anesthetic has reached the lungs it is moistened and thoroughly warmed to the body temperature. There is no irritation of the lungs, and mucus and saliva are usually absent. 4. When the ether evaporates from the oil in the colon a frigid condition ensues, which cools the mixture and retards evaporation. This process recurs automatically until all the ether has parted from the oil. During this time the temperature of the patient remains normal, as determined by a thermometer placed in the axilla. The skin is warm to the touch; the color of the face suggests thorough oxidation all the time. The cold, clammy sweat often noticed with ether given by other methods does not exist with oil-ether. 5. Quiet respiration, normal pulse, and good color during the anesthesia indicate that no toxic condition exists. The absence of nausea and vomiting, the absence of change in urine or blood, in conjunction with other clinical facts

noted, indicates that there is less toxicity with this form of anesthesia than with the usual inhalation methods. It is proposed to take advantage of the principle of synergism and to convert colonic anesthesia into synergistic colonic analgesia; in other words, to get a complete brain block by using much smaller amounts of ether than heretofore employed and adding to this effect of ether the synergistic effects of the combined morphine and magnesium sulphate. From his observations in this connection the writer deduces that when magnesium sulphate (from 1 to 2 c.c.) is used with morphine (from 1/12 to 1/8 grain), instead of plain water, and given by hypodermic injection, the value of the morphine is increased from 50 to 100 per cent. That is, one hypodermic injection will do the work of from two to four. Magnesium sulphate (from 6 to 15 c.c.), given by hypodermic injection two hours before operation, followed by morphine sulphate hypodermically (from 1/12 to 1/8 grain) one hour before the operation, when supplemented by nitrous oxide and oxygen (the oxygen being employed in a much higher percentage than usual), gives a safer and better relaxation than when ether is used. Synergistic analgesia is the logical evolution of general anesthesia. Analgesia with consciousness is present oftener with colonic anesthesia than with other methods of administering any of the general anesthetics.

3. Determination of Cure in Gonorrheal Infection of the Male.—Russell D. Herold concludes from his studies that cultures of prostatic and seminal fluids and first urine sediment, carefully collected, are the most reliable single means of determining whether or not a gonorrhea is cured. For this purpose, phosphate agar with blood and ascitic fluid is suitable, and the inoculated plates should be incubated under reduced oxygen tension. The complement fixation test is a valuable aid, but the results should be taken in conjunction with the cultural results. Low degree positive fixation may persist up to a year after positive smears and cultures can be obtained. However, with positive serological reaction cultures should be repeated at intervals, and the patient kept under observation until the serological tests give negative results. The gonococcus may be identified by agglutination tests with polyvalent antigenococcus serum. A satisfactory antigen can be easily prepared. The use of provocative tests before taking cultures and smears is of no advantage. The pus cell content of smears and macroscopic urinary appearances may be misleading, and constitute no safe index of cure.

4. Induced Atrophy of Hypertrophied Tonsils by Roentgen Ray.—Murphy and his associates base this report on the result of the following treatment on forty-six patients ranging from 3½ to 45 years of age, all showing more or less hypertrophy and disease of the tonsils and surrounding tissues. The factors governing the dose of roentgen ray given to the region of each tonsil were as follows: The spark gap, measured between points, was 8 inches; 5 milliamperes; 10 inches distance from the target to the highest point of skin exposed. The time of exposure varied from three to seven minutes, according to the age of the patient. The ray was filtered through 3 mm. of aluminum. The approximate value of this dose was from 1 to 1½ skin units. The patient to be treated was placed on a table in such a position that the ray entered under the angle of the jaw and penetrated through the soft tissues to the region of the tonsil. The area exposed on each side was about 3 square inches, the surrounding parts being protected by heavy sheet-lead. For young children a special board was used with retaining straps, and the head secured by means of a gauze bandage. No patients were treated during a time when the throat showed evidence of acute infection. The results suggest the possibility of utilizing the well-known fact that lymphoid tissue is easily destroyed by the roentgen ray for clearing the throat of an excess of this tissue. In the series reported only one patient received more than one treatment. From their studies on animals the writers believe it should be possible to induce almost any degree of atrophy by repeating the roentgen-ray treatments at suitable intervals. They attribute the disappearance of hemolytic organisms of the throat, not to the direct action of the roentgen ray on these organisms, but rather to the proper drainage of the crypts as the tonsil tissue atrophies.

2. An Address on the Psychology of Anesthesia.—Dudley Wilmot Buxton notes that gentle surgery protects the patient from reflex dangers, while some form of blocking the centripetal nerves by analgesics, as in Crile's anoci-association method is probably a protection against some shock effects, although, of course, the latter cannot be entirely abrogated in abdominal or thoracic operations. If the induction is performed hurriedly or without due attention to detail, and if the operation is commenced before absolute anesthesia has been obtained for some minutes, the whole course of the anesthesia proves unsatisfactory. Do what one may, it is marked by an uneven level of narcosis; vomiting or retching is constantly imminent, and disturbances, usually vagal in origin, are common. Throughout the anesthesia anxiety and dissatisfaction obtain, and severe aftereffects usually occur. The writer believes this trouble arises through no initial and complete control having been obtained over the higher centers. Consciousness may eventually be lost, but the influence of the unconscious mind is aroused; for some reason, at the nature of which one can only guess, its effects persist and are hardly abrogated. To recognize this state is to suggest its treatment, whether or not one admit its suggested causation.

5. A Case of Enteric Fever Due to the *B. Enteritidis* of Gaertner.—Rosher and Wilson report the case of a patient suffering from pyrexia which simulated closely a typhoid course, but which was probably due to infection with the *B. enteritidis* of Gaertner. The case, moreover, was of a purely sporadic nature, and was unconnected with any coexisting outbreak of food poisoning. It is suggested that it would be advisable, in view of this case, to test the sera of patients suffering from enteric-like infections against a more extended series of antigens than are commonly employed, in order to ascertain whether sporadic infections with organisms of the enteric group other than *B. typhosus*, *B. paratyphosus*, A, and *B. paratyphosus* B are more than mere pathological entities.

7. A Note on Spirochetes in the Etiology of Certain Paralyzes.—G. Schuster undertook a research in the parasitology and pathological tissues of general paralysis of the insane, at the Psychological and Neurological Clinic of the Royal Hungarian University of Budapest, soon after the publication of Noguchi's researches. His investigations were interrupted by the war and resumed at the end of 1918. He summarizes his findings as follows: 1. Large quantities of spirochetes are to be found in the central nervous system in cases of paresis, even when it runs a simple course without paroxysm. 2. The main colonies of the spirochetes settle in the lowest strata of the cortex, and while increasing in number there they may spread over other areas of the cortex; while alterations of the tissue of the cortex may be extensive the alterations of the medullary sheath are most obvious just on the edge of the cortex and medullary sheath. 3. He was able to show fine spirochetes in the lower layers of the cortex in a case of disseminated sclerosis; there seems to be some connection between disseminated sclerosis and alterations of medullary sheath, because in both cases the result caused by spirochetes is plexiform disintegration of the medullary sheath, of which the site of election is the boundary of the cortical and medullary substance. 4. Formalin injection prevents demonstration of spirochetes in the central nervous system.

1. The Diagnostic Significance of Abdominal Pain in Childhood.—Robert Hutchison reminds one that abdominal pain in a child may be due to nothing worse than an attack of acute indigestion set up by a green apple; or it may indicate an attack of acute peritonitis set up by a green and gangrenous appendix. It is a matter, therefore, which craves wary walking in diagnosis, for a mistake may be fatal, and between one's anxiety not to overlook a serious cause and one's natural reluctance to alarm the parents unduly, it is often difficult to steer a proper course. The difficulty is increased by the fact that the pain may be the only symptom of abdominal disease. Extra-abdominal causes of pain are especially apt to lead to error. These causes are divided according as the cause has its seat in the abdominal wall or in the thorax. Causes in the abdominal wall are spinal caries, lateral curvature, rheumatism, herniæ through the abdominal wall, hip disease, and herpes zoster. Discussing thoracic causes, the writer states that the commonest form of error is to diagnose a case of pneumonia occurring at the right base as one of appendicitis. Vomiting, which is a very constant and conspicuous feature of early pneumonia in childhood, helps still further to simulate the picture of abdominal disease. There is reason to believe that the abdominal pain in these cases occurs only when the diaphragmatic pleura is affected. Pericarditis, when the diaphragmatic surface is involved, may simulate abdominal disease, although it is much less common as a source of error than pleurisy or pneumonia. The intra-abdominal causes of pain are divided, for the sake of convenience, into cases of sudden or catastrophic pain, and cases of chronic or recurrent pain. By the "catastrophic" cases Hutchison means those in which the pain sets in suddenly and is of great intensity. They are cases often spoken of as "abdominal catastrophes," and include many examples of what are known in surgical slang as "the acute abdomen." The possible causes of an abdominal catastrophe are fewer in the child than in the adult. The possibilities which one has to consider when confronted with a case of severe abdominal pain of sudden onset at this age are acute indigestion, appendicitis, and some form of acute intestinal obstruction, of which that due to intussusception is specially frequent in the child. Among the rarer causes are abdominal or Henoch's purpura. Chronic or recurrent abdominal pain in childhood is rarely traceable to the stomach, the seat of origin usually being the intestine. The intestinal cases are divided into those due to (a) ordinary colic, (b) "umbilical" colic, (c) enterospasm, and (d) chronic obstruction. The cases which cause the greatest anxiety are those in which the question arises whether a chronic or recurrent pain has its seat in a diseased appendix. Worms are often believed by parents to be a cause of abdominal pain in childhood, but the writer's experience does not bear this out. Enlarged glands, on the other hand, more commonly give rise to abdominal pain than is generally realized. Affections of the urinary tract are a frequent and often overlooked cause of abdominal pain in early life. Movable kidney and attacks of true renal colic are rarely to be reckoned with; on the other hand, kinking of the ureter and ureteric calculus are frequent causes of abdominal pain in childhood. In the male urethral obstruction as a result of phimosis or a narrow meatus may cause attacks of hypogastric pain from overdistention of the bladder. In girls one sometimes has to think of pelvic causes such as salpingitis.

4. Massage of the Heart and Resuscitation.—J. A. Gunn lays down the following directions for resuscitation in cardiac arrest in man or animals, whether from chloroform anesthesia or from any other condition in which cardiac arrest is "accidental." If the heart has stopped, artificial respiration should be resorted to im-

mediately by the usual methods. If, at the end of three or four minutes, no pulse can be felt, and especially if no heart beats can be heard on auscultation, adrenalin should be injected into an external jugular vein, by an assistant available; if no assistant be available, the gain from adrenalin more than compensates for the loss of time, provided the materials are at hand, as they ought to be. In the meantime, or subsequently, as the case may be, the abdomen should be opened high up, one hand inserted in the opening, passed up over the left lobe of the liver, and the heart felt for above the diaphragm. The heart should then be massaged intermittently. As soon as spontaneous beats of the heart, however feeble, are felt, massage should be interrupted for several beats to allow the contractions to establish themselves; otherwise, continuous massage may abolish them again. The heart should then be massaged again for a short time, when the beats will probably improve. When the heart has begun beating it is safer to use too little than too much massage. The hand should not be removed from the abdomen till the heart is beating well. When the heart continues to beat regularly and strongly an intravenous injection of atropine should be given. Artificial respiration must be kept up continuously also after the heart begins beating. After five minutes it may be interrupted to see if natural respiration will begin, but not for long. No harm is done by keeping up artificial respiration, even if it inhibits the natural respirations, whereas, on the other hand, it is not safe to interrupt artificial respiration very long, if natural respiration does not commence. Natural respiration may be expected to begin in five to ten minutes after the heart begins to beat again, but may be delayed for thirty minutes. During the manipulation, and afterward, if these procedures be successful, care must be taken to maintain the body temperature.

2. An Unusual Case of Rupture of the Gall-Bladder. Karl R. Ruddell.
3. Anesthetic Notes. Arthur E. Guedel.

1. Heroic Treatment of Malaria in the Tropics.—G. C. Graves states that, after careful study, much experimenting and comparing of the several methods of treatment, the so-called follow-up treatment of patients who have been discharged from the hospital in which some doubt exists as to whether a cure has been completely accomplished, has proved highly satisfactory. The plan is given in brief as follows: Upon the discharge of a patient who has been treated for malaria (only positive blood cases being considered), the overseer of the mines or foreman of the railroad from which the laborer was sent to the hospital is notified that the man was treated in the hospital for malaria, and he is requested to place the man on the quinine list and to give him 30 grains of quinine in solution (fifteen grains in the morning and fifteen grains in the evening) on every Saturday and Sunday for eight weeks. A copy of this request is sent also the superintendent of the mines or of the railroad, as the case may be. Each farm keeps a supply of the quinine solution. As soon as the discharged patient has finished his eight weeks of treatment his name is erased from the quinine list.

7. Some Underlying Principles of Gastric and Intestinal Surgery. J. Shelton Horsley.

1. The Mechanical Treatment of Tuberculosis.—Foster Murray, on the premise that the mechanical treatment of tuberculosis is accomplished chiefly by the employment of artificial pneumothorax, confines his dis-

cussion to this method. The attainment of successful results in this form of therapy depends largely upon the proper selection of cases. It is now fairly universally agreed that the following types are suitable for induced collapse: (1) Cases of severe, massive hemoptysis where it is definitely known, through physical and radiographic examination, from which lung the hemorrhage arises. (2) Cases of small or moderate hemoptysis recurring in spite of all less radical measures directed toward their control. (3) Unilateral active ulcerative lesions which, regardless of the prolonged application of a rigid rest-dietetic-hygienic regime, progress steadily, even extending and destroying. The more immediate happy effects resulting from successful collapse are many and sometimes startling in the rapidity of their accomplishment. A rather prompt reduction in temperature and pulse rate invariably follows. If other expressions of toxemia be present, such as dyspnea, night sweats, and neurasthenia, definite and comparatively rapid improvement may reasonably be expected. Weight and strength are regained. Cough and expectoration may at the beginning be moderately increased; later, both become markedly lessened and in a fair percentage of cases finally completely checked. The general results of pneumothorax therapy, when there is taken into consideration the unfavorable types in which it has been regularly employed, are encouraging. The lives of such patients have, in many instances, been greatly prolonged. A fair percentage of patients have been restored to lives of certain usefulness. A small percentage have become apparently permanently cured. Yet these are all cases which would otherwise most likely have proceeded to fatal termination.

Wiener klinische Wochenschrift.

December 2, 1920. iii, 49.

The Oligodynamic Action of Sublimate.—Weltmann of Professor Chvostek's clinic takes up the subject of Saxl's researches in the field of "oligodynamic distance action" of the salts of certain metals, which in turn appear to be an outgrowth of Naegeli's work with the same substances as inhibitors of the growth of minute plants like the algae. This botanist invoked a special form of energy termed by him "isagy," and advocates of infinitesimal dosage in medicine appear to have derived some doubtful comfort from these finds. Saxl calls special attention to an action exerted at a slight distance, a stratum of air and a piece of filter paper being interposed. The tests mentioned have to do with ordinary chemical reactions and we have to assume either a volatile or an evaporative activity of the salt, or the presence of some as yet undescribed force. In repeating Saxl's experiments the author placed a number of sublimate tablets in a Petri dish and covered the latter with a sheet of filter paper. Powdered glass was now placed on the paper, which at no point came in contact with the tablets. Three days later the filter paper was found to possess remarkable bactericidal powers over the bacillus coli, a power not shared by the glass. The paper was also found to be strongly hemolytic. The most sensitive tests failed at first to reveal the presence of mercury in the paper. Later the tests became positive and the glass was also found to possess the same biological properties as the paper. Naturally it must be shown that these properties conferred on the paper and glass are not due to evaporation. In starting out with this aim the author was able to demonstrate that the mysterious behavior was due to simple evaporation; the assumption of an unknown force is therefore gratuitous.

Skigrams, Etc., Admissible Evidence in Malpractice Case.—In a malpractice action, charging that defendant hospital's surgeons left a piece of gauze in a sinus, it was held that skigrams of the plaintiff's teeth, made for the purpose of determining whether or not the plaintiff had septicemia, also testimony as to the plaintiff's physical condition as evidenced by her ability to work before and after the surgical operation, and the piece of gauze taken from the sinus, were all properly admitted in evidence.

Society Reports.

SOUTHERN SURGICAL ASSOCIATION.

Thirty-Third Annual Meeting, Held at Hot Springs, Virginia, December 14, 15 and 16, 1920.

THE PRESIDENT, DR. WILLARD BARTLETT, ST. LOUIS, MO., IN THE CHAIR

Fractures of the Skull; Report of Cases.—Dr. C. E. CALDWELL of Cincinnati stated that skull injuries might be divided into two primary divisions, those in which the traumatism to the neural centers was of such severity that the patient was obviously doomed, and died within a few hours of the receipt of the injury, and those in which the injury was of such a nature as to permit of the patient living to present those problems of intervention or nonintervention which were to determine the ultimate results of treatment. These problems were obviously those of correctly estimating the amount and character of the brain lesion. Certain well known clinical signs were helpful in arriving at conclusions. The presence or absence of paralysis or spasticity, the presence of brain irritation, as shown in the contracted pupil and exaggerated reflexes; the succeeding phase of brain anemia, as seen in the dilated pupil and failure to react to light. The evidence of cerebral compression in the increased blood pressure, and increased pressure of the spinal fluid on spinal puncture. All these various phenomena were those by which the surgeon was guided in determining his conduct. The 41 cases reported in this paper represented the cases of head injuries with fracture which had come under his personal care since January 1, 1918. Of these 41 cases, 7 were operated, and 34 not operated. Of the 7 operated on, 5 recovered and 2 died. Of the 34 not operated on, 24 recovered and 10 died. Of the 10 who died, 8 died within two or three hours after admission. The other 2 lived respectively four and five hours and would have been decompressed had he been called earlier. Of the 2 who died after operation, both had severe intradural hemorrhage, and 1 had a steadily rising temperature from the time of admission, possibly due to the lighting up of old mischief in a formerly diseased mastoid into which the fracture line ran.

The Late Results of a Series of Head Injuries.—Dr. C. C. COLEMAN of Richmond, Va., said that the incidence or severity of the late results of head injuries could not be predicted upon the type or degree of an acute injury. Epilepsy as a late complication in the series reported had lessened incidence in the cases with early operation. To have value this observation must be substantiated by a larger series. Compensation had a direct etiological influence on the development of post-traumatic neuroses, but this influence could be determined only by careful neurologic study. The prevention of late effects of head injuries was closely linked with the early treatment and aftercare. The pathology and evolution of many head injuries of civil life were as yet impossible of demonstration by present methods.

Dr. ROBERT T. MORRIS of New York City stated that intracranial pressure in these cases, which was relieved by decompression, was frequently due to an irritative lesion, and that lesion was due to contraction of dural adhesions, and unless one recognized the presence of dural adhesions in many of these cases of epileptic and epileptoid seizures and various psychoses coming on as late symptoms, headache, nausea, etc., an important factor was overlooked in the condition of these patients. In cases in which the dural adhesions covered only a small area one sometimes had a marked demonstration from the relief of pressure. Where secondary changes had taken place, if the parenchyma had been injured seriously, with fatty changes in the cortex and cells of Purkinje destroyed, one was not going to have good results from the separation of dural adhesions alone. Where there was simply an irritative lesion of limited area, decompression was not the operation, but a separation of dural adhesions, and the application of methods for the prevention of their recurrence.

Dr. HENRY O. MARCY of Boston said that Hunter McGuire told of one of the most remarkable cases of

head injury on record. A man in one of the southern battles was struck on the head with a missile. He was brought into Richmond unconscious. He made a slow recovery. He lost his ability to speak; he lost his mentality so far as reasoning and thinking were concerned, and lived an animal life for thirteen years. Dr. McGuire operated on him at the end of that time, and the man on waking from the ether exclaimed, "Where has the Army moved today?"

Dr. W. P. CARR of Washington, D. C., said he would like to confirm what Dr. Morris had said about separating dural adhesions. It had been his experience to observe great improvement by separating dural adhesions with his finger in some cases, while in others he had found them so tough or dense they had to be cut with a knife or scissors. Decompression, a necessary part of the operation, had a good deal to do with recovery of these cases because in most of them one found an edematous condition of the brain, and a great deal of that fluid would drain off during the operation.

Dr. JAMES E. THOMPSON of Galveston, Texas, stated there were certain cases that would naturally be fairly well understood by the surgeon the moment he saw them, but in the severe cases no one would dream of interfering except by spinal puncture, where the patient was practically moribund and would probably die within an hour or so. In the other class one felt reasonably certain he could ward off the symptoms by spinal puncture to relieve pressure. In all probability, these cases eventually fell into two classes, one of which got better without further interference, and the other would necessitate subsequent interference. The main difficulty was in understanding in the second class of cases what had really occurred. In other words, what was the condition of the brain after a cerebral injury?

Dr. J. W. HENSON of Richmond, Va., said he would like to ask Dr. Morris to tell how he would locate dural lesions.

Dr. MORRIS replied that almost always there was local tenderness on pressure and the scalp was tender over that point.

The Work of the American Society for the Control of Cancer.—Dr. CHARLES A. POWERS of Denver, president of the society, read this paper (see page 211).

Cancer Infection.—Dr. ALBERT L. OCHSNER of Chicago, said that cancer developed very constantly on the proximal side of the pylorus and on the distal side of the ileocecal valve, while it developed only rarely between these two points. The fields in which it would develop contained substances that were acid in reaction, while the intestinal contents in the intervening portion was alkaline. Every precaution should be taken against cancer infection, notwithstanding the fact that its infectiousness had not been proven. According to Virchow's theory, cancer was due to local irritation either mechanical, as in the form of friction or pressure, as in smoker's cancer and the cancer of betel nut chewers, or chemical, as in paraffin workers, chimney sweeps, and electric irritation, as in x-ray workers, or heat, as in workers in certain trades. Cancer occurred almost exclusively in portions of the body exposed to the irritation of the outside world. This included the gastrointestinal canal which came in contact constantly with filthy food in locations in which stasis insured long continued contact and persistent irritation. One found a notable example in the enormous amount of cancer of the stomach in manure eating people, i.e. people eating raw vegetables growing in soil fertilized with night soiling or with barnyard manure. A marked example of this was found in the Japanese who ate such vegetables in abundance and who suffered greatly from cancer of the stomach, while the inhabitants of India, whose religion commanded them to boil food and drink, were notably free from stomach cancer. Sewerage was said to be an important factor in the production of cancer.

Cancer of the Uterus.—Dr. JOHN B. DEAEVER of Philadelphia said that the cervix was the more common site of uterine carcinoma, and in this location it spread very rapidly, caused earlier fixation of the uterus and extension into the broad ligaments and walls of the vagina. Carcinoma of the cervix in the vast majority of cases developed in women who had had children. Very often there was present a laceration not entirely

healed and presenting a reddened eroded surface covered with a discharge and giving evidence of chronic inflammation. In the presence of undoubted cancer, complete hysterectomy was probably as sure a means of curing the disease as we had, provided that the growth was not so far advanced as to threaten adjacent tissues. It was these cases also that the radiologist believed were the most amenable to their treatment. This might be so, but it had not been his experience. He had too often seen an apparent regression of the tumor for several months after radium treatment, only then to be confronted with evidence of recurrence. This might possibly be due to faulty technique, but the same held good to a large extent with regard to surgical failure. His remarks were based on 500 hysterectomies performed by him since January 1, 1916. These 500 cases comprised: carcinoma of the uterus, 27 (no deaths); myoma uteri, 367; diseases of the uterus, tubes and ovaries, 106, among the last being six ovarian cysts associated with malignancy. The operative mortality of the entire series was 2 per cent., 10 deaths.

Radium in Carcinoma of the Uterus.—Dr. WILLIAM KOHLMANN of New Orleans said that radium was being more frequently used in the treatment of malignant disease than formerly, and the excellent results achieved in many cases impressed the profession with its importance as a valuable adjunct of surgery in the treatment of malignancy. In many instances it might be compared very favorably in its effects with the results obtained by surgical measures, and frequently in cases where surgery failed it would bring about relief and even apparent cure. Great care was necessary in the application of the radium because of the formation of cicatricial tissue due to the previous operation and the close proximity of the bladder and rectum. The effect of radiation in cases of carcinoma was noted clinically in a few days after the application. Three or four days after the treatment the infiltration and tumefaction of the cervix were found diminished, a process which was gradually followed by the shrinking of the mass and infiltration of the broad ligaments. This action of radium was most probably due to destruction of the carcinoma cells and to increase in the formation of connective tissue which, by shrinking and cicatrization, had a tendency to interfere with the life of the carcinoma cells. Since June, 1915, 96 cases of carcinoma of the uterus had come under his observation in private and hospital practice, and of this number 56 were treated with radium only. All of the cases were examined microscopically and the clinical diagnosis of carcinoma was confirmed. With very few exceptions, all cases were benefited and improved in regard to the general and local symptoms. Some of the cases had improved to such an extent that a cure could be hoped for. Cases which did not show any improvement, even after prolonged treatments, had not been influenced even after prolonged treatment. Of 22 cases living to-day, 1 was well for four years, 1 for three years, and 2 for two years. The remaining cases had been under treatment for less than twelve months. Of 22 cases which had died, 2 had been well for three years, but died of intercurrent pneumonia. One, a woman of 39 years, died free of recurrence in one and a half years, the cause of death unknown.

Electric Conductivity Observations of Malignant and Benign Tumors: With a Further Note on Operations for Cancer of the Large Intestine.—Dr. GEORGE W. CRILE of Cleveland stated that regarding the practical application of the electrochemical theory, from one to two days before the operation large quantities of water were given by mouth, by rectum, subcutaneously, or by means of a Rehfuss tube. If the patient was greatly reduced, a transfusion of blood was given before the operation, and if required, transfusion also was given after the operation. If the myocardium was impaired, digitalis was given until the action of the heart was improved sufficiently for the safe performance of the operation. The operation was performed in two stages, allowing a sufficient period after the preliminary colostomy to insure the reaccumulation of the reserves of the patient. The operation was performed under nitrous oxide-oxygen analgesia plus local anesthesia. A wide incision was made to insure the minimum handling of tissue. After operation, hot packs were ap-

plied to the abdomen in order to increase the functional activity of the liver. In cases of cancer of the rectum, radium was employed both before and after the operation. In cases of cancer of the large intestine, radium was applied after the operation. If these procedures were carried out in detail, the patient left the operating room in approximately the same condition as he entered it and his convalescence was well secured. His associates and he had performed 175 operations for cancer of the large intestine. Of these, his personal series had been 73, of which 53 operations, including 24 colostomies, and 29 radical operations without a death, had been performed since the adoption of this general method based upon the above physical interpretation.

Cancer of the Pelvis of the Kidney.—Dr. ALEXIUS MCGLENNAN of Baltimore said that no definite relation could be found between the development of the papillary tumors and the presence of stone in the kidney. That leukoplakia might be the result of calculus irritation and in turn be the source of a squamous cell tumor was a possibility. Nephrectomy was required for the removal of these tumors. The ureter should be carefully investigated and as much of this organ as was indicated should be removed because of the danger of an implanted growth in its lumen. In many cases complete nephroureterectomy should be done. Some authorities believe the latter should be the operation of choice in all cases. The symptoms of papilloma of the renal pelvis were fairly typical. Hematuria was almost constant, and the quantity of blood lost might be sufficient to disable the patient. There was some blood in the urine almost all the time, and at intervals profuse hemorrhage occurred and might persist for days or weeks. The profuse bleeding was usually preceded by a colicky pain, and this intermittent hematuria was considered a characteristic symptom. The presence of transitional epithelium in the urine was a valuable corroborative symptom.

(To be continued.)

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held December 29, 1920.

THE PRESIDENT, DR. CHARLES H. CHETWOOD, IN THE CHAIR.

ON motion the time of the Executive Session was extended to include the program of the evening, which consisted in a "Symposium on Medical Legislation: Its Effect upon the Public and the Profession."

Amendments to Workmen's Compensation Law.—Dr. EDEN V. DELPHEY called attention to the fact that a part of the amendments to the Workmen's Compensation Law which he had presented at the last meeting, in behalf of the Committee on Compulsory Health Insurance and Workmen's Compensation, had not been acted upon. The amendments were approved by the Society together with the recommendation that they be brought before the Legislature.

Remarks of Retiring President.—Dr. CHARLES H. CHETWOOD said he would take this opportunity to thank the assembly for its kindly toleration as well as for its support during his term of office. The business of their meetings during the past year had been divided into scientific and executive functions. The scientific program had covered practically all branches of medicine and had called forth some noteworthy contributions, which had been well discussed. As to the Executive Sessions, this had been a year which would always be distinguished because of the ratification of the new Constitution and By-Laws. In this action they had taken what might be termed a conservative-progressive attitude. During the year Dr. Chetwood said he had conferred with the executive officers and committees of the Society on many occasions and all were deserving of honorable mention for the way in which they had performed their several duties. The coming year, he prophesied, would be one of fruitful attainment for the Society. In laying down the duties of presiding officer he assured the members that he always stood ready to give his services to the Society in any way that they might desire.

The Health Center Bill of 1920.—Dr. E. LIVINGSTON HUNT gave a résumé of the Sage-Machold bill and of the arguments for and against it. He said it was impossible to do the bill justice in the ten minutes allotted to him, but as the bill was dead it probably did not warrant that more than that time should be devoted to its analysis and summary. It was called an act to amend the Public Health Law so as to provide for the residents of rural districts, industrial workers, and others not able to secure proper medical service, medical treatment, hospital facilities, and nursing care, and in general to improve the health of the community. Briefly the bill proposed to establish Health Centers in the counties and cities desiring them. A board of supervisors might establish a health center which should follow a general plan. This included hospitals, laboratories, x-ray plants, district nursing, child welfare work, etc. The entire plan was to be under the supervision of the State Commissioner of Health and the expense was to be shared by the county or city and the State. No community was obliged to adopt the plan; it could be adopted in part, if desired, and it could be rescinded. In fostering the proposed law the State Department of Health presented a constructive plan to meet certain conditions believed to exist. It was claimed that rural districts had a much smaller number of physicians than formerly, that young men were not settling in the country in sufficient numbers to replace the older ones lost by retirement or death, and that in consequence mortality was greater in rural than in urban localities. It was further claimed that the establishment of these health centers would encourage physicians to settle in rural districts, with consequent adequate and more efficient medical care for the people, the advantage of group practice for the physician, and the advance of the medical art. The scheme had both its merits and its disadvantages. All the work was to be inspected and standardized by the State Department of Health, and costs paid on the written approval of the State Commissioner of Health. The arrangement, it was claimed, would not affect in any way the relations of physician and patient. This was very briefly the bill of 1920 which no longer existed, but it was said that there would be another bill similar in substance to this bill but differing in detail. In counties the supervisors would appoint the Board of Managers of the Health Center and in cities the Board of Managers would be appointed by the Mayor. It was required that the Board of Managers should consist of eight members, including the judge of the county, the health officer, two physicians duly licensed, and one woman. In considering the arguments for and against the bill, there were three particular questions that came up: (1) Would this legislation affect the community favorably or adversely? (2) Would it affect the medical profession favorably or adversely? (3) Assuming that there was a conflict between the interests of the community and the medical profession, what were we as medical men to do about it? From the standpoint of benefit to the community it was claimed that the establishment of these health centers would encourage physicians to settle in rural districts, with consequent adequate and more efficient medical care for the people, and that the physician would have the advantage of group practice, which would tend to advance the medical art. We also had from the standpoint of benefit to the community the fact that some legislation of this sort would be enacted to meet existing conditions and the demands of the people and of the State Board of Health. On the other side, it was claimed that the bill gave too much power to the laity and too little to the medical profession. It was claimed that it gave too much power to boards of supervisors and boards of health and to the State Health Department. This part of it might be all right with the present Health Commissioner, but how about a different health commissioner? It was claimed by some that it was a step toward centralized government and paternalism, which was the tendency of the times. There was a question whether it was not akin to government ownership of the railroads; and whether it was not interfering with personal liberty. Was it not a step toward State medicine; or if it was not State medicine was it not county medicine? Again it was pointed out that it might be

unfair to certain physicians. If one physician in a community was connected with a Health Center Clinic, why not another? Might it not be that the fact that one physician was assigned to the clinic and another was not would give to the man connected with the clinic a distinction and prestige over the other physicians in the community which was perhaps not deserved? Furthermore such a plan put a larger number of physicians on a salary and thus did away to a certain extent with individual initiative. A plan backed by the State would not command the best medical service. The State never had commanded the best medical service and never would. Finally, such a plan would involve an additional burden to the tax-payer.

The Need of Public Health Centers.—Dr. EDEN V. DELPHEY read this paper, in which he said that from time to time various and sundry amateur and professional uplifters had endeavored to prescribe for the political, industrial, and bodily ills of mankind, and not infrequently their prescriptions were based either upon an inaccurate and incomplete investigation of all the facts in the case with a resulting inaccurate diagnosis of the underlying pathological condition, or upon an incomplete appreciation of the collateral effects not only upon those whom they wished to assist but also upon those whom they wished to assist them. In endeavoring to arrive at a proper conclusion as to the desirability of any proposition for the betterment of mankind, it was absolutely necessary to consider very carefully and weigh all the facts in the case, their relation to each other and to the surrounding elements of society, the nature and variety of the employment of the persons, the income, the mode of living, sanitation, environment, cost of food and clothing, medical attendance, drugs and medicines, the amount spent for these and other luxuries, for extravagances, for dissipation—mild, such as movies, and more serious, as for alcoholics, and for irregularities such as gambling or immoralities. Until such a complete survey had been made, it would be absolutely impossible to determine the need of the proposed measure. In making such a survey it was imperative that the surveyors should be thoroughly competent for the purpose and that they should have the inclination, training, and capability for the work, and not as was the case a few years ago when it was proposed to utilize fourth year high school students in making a sanitary survey of the West Side. In medical matters it was necessary that the surveyor should be a broad-minded, ripened, and experienced physician in order that he might be capable of determining and weighing all the facts and of ascertaining whether or not the person was really in need of medical care and whether he would accept it, or whether he preferred to depend on home treatment, quack medicines, "new thought," or "Christian science." In promoting the propaganda for health centers these conditions did not seem to have been fulfilled. Moreover, the propagandists did not seem to appreciate the fact that prevention was better than cure; that their utopian schemes were not calculated to prevent the incidence of disease which they wanted to relieve after it had occurred. The researches of the Committee had shown that while the number of physicians in rural districts was less than formerly, this change was due to the rural physicians moving to the cities and towns because there they could more easily earn a reasonable living without such an immense expenditure of energy and vitality; and because there were fewer recent graduates going to the rural districts. These results were due to the more strenuous life of the medical practitioner in the rural districts; the question of fees and collections; and to the fact that the true physician went to see a sick person whether that person could pay or not. The lessened number was also due to the law of supply and demand and whether the person demanding was willing to pay a reasonable price for the supply. The spreading abroad of the fact of the lessened number of physicians in the rural districts was due to the desire of the amateur and professional uplifters to arouse the enthusiasm and support of those who had been deemed to be "amiable weaklings in business matters, easily gulled by piteous tales and flattering remarks about the magnanimity of the profession," and thus to inveigle them into supporting an impracticable and dangerous scheme. If the obstacles

to the successful practice of medicine were increased by such schemes as compulsory health insurance, health centers, and State medicine, the quality of the men who would choose the medical profession would be materially reduced and when that happened the whole people would suffer from their inefficiency. In the replies received to their circular letter the Committee had found that on the average there were $2\frac{1}{2}$ hospitals in each county and that these had the confidence and support of the people; that the people in the rural districts got to their physicians more easily, and the physicians to their patients more easily than formerly, except when confronted by the deep snows of winter, on account of automobiles and the State roads throughout the State. The majority of cases did not need the so-called advantages of "group medicine" nor of hospital treatment. Moreover, even if it were necessary to have all the highly qualified specialists specified in the propaganda for health centers, where would they be able to get real and not pseudo-specialists? Would they be made over night as it was reported some of the specialists in this city were? The highest degree of civilization was not indicated by the city having the greatest number of hospitals, almshouses, and insane asylums; not the one having the greatest number, but the one having the least need of them. The purpose of the State Department of Health was prevention; it could best accomplish the purposes of its creation by performing and adhering to these duties. Of late years there had been too great a tendency to "put it up to the government" and too little to the person himself—to the socialization of everything. Every attempt at nationalization, including our own during the world war, had resulted in inefficiency and decreased production. Was it not about time to call a halt to all these socialistic schemes? Was not the greatest efficiency through self interest? Were not these simply the desires of someone to "put over" schemes for "fat jobs" or were they merely the maundering expression of the weak and incompetent to get something directly or indirectly for nothing? The State Department had been holding itinerant clinics in various parts of the State, and the newspaper report of the one held at Goshen stated: "In the majority of cases the diagnoses of the local physicians were confirmed" (*New York Times*, Sept. 12, 1920). Dr. Delphely most emphatically registered his protest against the idea that the country physicians were the ignoramuses which so many of the city residents were so fond of assuming. On the contrary they were at least equal to, if not more competent than the average city physician. In concluding Dr. Delphely emphasized the great and crying need of further means of educating the public in matters pertaining to sanitation and the prevention of disease. There was no need of health centers.

"Better keep them all well than cure them when sick,

For the results of experience are thrilling.

To cure up the sick is good, but it's better

To prevent the people from illing.

Better stop the cause and source of infection

Than add more men to death's rally;

Better put a strong fence at the top of the cliff

Than an ambulance down in the valley."

The State Board of Health.—Dr. HERMAN M. BIGGS, State Health Commissioner, spoke of the health center from the standpoint of the State Board of Health. He first expressed his approval of the very excellent résumé Dr. Hunt had given of the Sage-Machold bill and the impartial way in which he had construed the bill. He said he thought there was a great deal of misconception in the profession in regard to a measure of this sort, what it was and what it would do. The way in which this bill came to be drafted was about as follows: When the Public Health Council was organized in 1914 it was granted the power to determine the qualifications of sanitary supervisors and other public health officers. One of its first duties was to establish minimum requirements, and it decided upon certain minimum educational requirements and a six weeks' course in public health. Through the Public Health Council such courses were established at the University and Bellevue Hospital Medical College and at the medical schools at Albany, Syracuse and Buffalo. Since that time more than 600 of the little over 1,000

health officers in the State had taken these courses. They found when it came to the enforcements of these regulations the first stumbling block was that in many communities there was only one physician and he was the health officer. It was found furthermore that these health officers were far beyond the age limit. The Public Health Council had placed the age limit at 65 years, and those over 65 years of age were ineligible. Then in 1916 came the poliomyelitis epidemic, and after that the war and the influenza epidemic. Owing to these, the demands that came to the Department of Health from all quarters for medical and nursing assistance were so numerous and so urgent that, first in 1916 and then in 1918, the Governor authorized the expenditure of \$50,000 for the purpose of providing medical service and nursing care in the various municipalities where they were not available. Then they made a further study of the situation and found that the drift from the country to the city affected not only the rural population in general but the medical population to even a greater extent. In many localities where there had been two or three physicians the younger men went into military service and did not return to where they had lived before. They had become acquainted with another kind of life and liked the advantages it offered in the way of association with their confrères so they became unwilling to go back to the country and they went to the cities. It was then found that the demand for medical service was more insistent and widespread than ever, and they made a census of the medical practitioners in twenty rural counties in the State, of which that in Livingston County was perhaps typical. In Livingston County there were 54 physicians in practice and of these only five had entered the practise of medicine or entered the county within five years; and of those who had entered the county some had been in practice elsewhere for many years. The average years of practice of the 54 physicians was 28 years. On an average the physicians of that county were over 50 years of age. When one took into consideration that, according to the data of the American Medical Association, the average life time of the physicians of the country was 59 years it meant that a large number of physicians in this county would die within the next eight or ten years. Then a survey was made of all the rural communities and they found that the duration of practice of over 25 per cent. of the physicians was over 25 years, and that less than 3 per cent. had entered practice in the last five years. Sixty-eight municipalities had appealed to the State Department of Health to provide medical care, because they had—no inadequate medical care, but no medical care at all. In this State the population of the rural counties had increased four or five per cent. while the number of physicians in practice had decreased about 15 per cent., and these physicians for the most part had been in practice over fifteen years. In other words, with the advance in the requirements of medical education there had been a decrease in the number of physicians entering practice in rural communities. A man who had spent seven or eight years preparing to practise medicine would not willingly go into a rural community where he was absolutely cut off from association with his medical confrères and had absolutely no laboratory facilities of any kind. It was not that he did not make a living in a rural district, for as a matter of fact he did relatively far better in the country than in the city, but a man properly trained and having had a hospital service would not go back to the practice of medicine as it was twenty-five or thirty years ago, and that was what the practice of medicine in a rural community meant. The practice of modern medicine presupposed laboratory facilities. There were twenty-seven counties in the State where there were no laboratory facilities, and in others there were only those furnished by the Public Health Laboratories, whose work was confined mostly to diphtheria and tuberculosis, and more recently Wassermann tests, etc., were being made. It was the discovery of this situation that made them think seriously of what could be done. Then there was not only the lack of physicians, but nurses were not to be had. They had increased the number of public health nurses from 75 to nearly 1,100 but they had had the greatest difficulty in getting

them. For private work it was almost impossible to obtain nursing service. Then the present cost of private nursing service was entirely out of the reach of most people in rural communities. The inability to employ private nurses, the lack of domestic help, and the distance of the doctor had made the demand for hospitals greater. It was this situation which had brought them to the health center idea. The Sage-Machold bill was drafted and submitted to the Public Health Council which modified it and then presented it. It was not primarily public health legislation. Dr. Biggs declared he did not regard it as such and never had regarded it as such, although there was a part of it which might be considered public health legislation, namely, that part referring to the creation of health districts, the provision that compensation should be provided by the State, and certain other details of administration. In reference to the provision for compensation of health officers, health officers were now getting \$50, \$100, 150, and \$200 a year and the only reason they were getting that was because the Public Health Council had introduced into the public health law a provision that the minimum compensation should be not less than 10 cents per capita. An attempt had been made to repeal that law but it was not successful, and now under the bill the State was to pay 10 cents per capita and the municipality 10 cents, and the officer would thus receive 20 cents per capita. In so far as that was concerned the bill was a public health measure. In other respects the bill could not be considered a public health measure, but an attempt to provide medical service in the State where it was now wanted. Dr. Biggs stated that personally he was not interested in the bill except as he was interested in a general way in public welfare, but there were two points which he wished to emphasize strongly. The medical profession had been very unfortunate in the general attitude it had taken. He could remember that seven years ago he had spoken in this hall in a discussion on the reporting and supervision of venereal diseases, and a paper was read opposing the supervision of venereal diseases. A committee was formed which went to the Mayor and asked him to rescind the action of the Health Department, when all that the Board of Health asked at that time was that venereal diseases being treated in clinics and hospitals be reported, giving the initials of the patient, and also offering laboratory facilities for aid in the diagnosis of venereal diseases. Nothing could have been sharper than the general attitude of the medical profession in its demand to have that order rescinded. The same thing happened in connection with tuberculosis some years ago, in 1898 and 1899, when physicians were sent to Albany to prevent the enactment of legislation giving health authorities power to deal with tuberculous persons. This general attitude of the medical profession was probably due to the kind of work they did. The physician was so absorbed in his work for his own patients that he did not get a broad comprehension of the situation in the State. Consequently his attitude was one of obstruction. The speaker said he did not pretend that this bill was model legislation, but it was the best they were able to devise at this time. No action of a negative kind was going to change the situation; if the medical profession and the State Health Department did not change the situation somebody else would take action. Dr. Biggs pointed out that the farmer and the Republican vote controlled the legislature and it would make no difference to them whether the medical profession wanted it or not, and he advised the medical profession that if they came to the Legislature they should come not to obstruct but to offer something constructive. As a rule the medical profession did not show very great interest in legislation, even when vital interests were involved. As an illustration Dr. Biggs described the difficulties he had encountered when he undertook to oppose the Chiropractor bill last spring. At that time, he stated, not a single member of the medical profession was present at the hearing to oppose this bill. In closing he urged that the Comitia Minora or some committee of the Society should propose some constructive legislation or criticism, and assured them that if they came simply with opposition it would not much longer be effective.

Impending Public Health Legislation.—Dr. HENRY

LYLE WINTER spoke on this subject. He said that he had come this evening on the invitation of the President more for the purpose of learning than in the hope that he could say anything of particular interest except on one or two minor points. The officers and standing committees of the State Society were not conversant with the attitude of the members of the various county societies, and for that reason he was glad of an opportunity to learn the attitude of this Society. He thought there ought to be some method established in the various county societies which would assist the chairmen of the standing committees in the State Society by giving them some sort of information as to the views of the members of the county societies on matters of importance to the profession. It would be a good plan if the county societies and others would send full reports to the State *Journal* of their action on public health matters, those reports to be sufficiently enlarged upon to convey the attitude of the society so that others throughout the State might be informed. This would help the Council and committees of the State Society in any action they might take. The interests of the profession were so different in different parts of the State that something of this kind was needed. Dr. Winter said there were three subjects upon which he wished to speak: (1) Annual reregistration. (2) The Health Center Bill. (3) The Chiropractor bill. Health insurance had been pretty thoroughly discussed. It would probably come up this year, but they all knew where they stood on that question, and there was not the slightest possibility of such a bill going through the Legislature. The Annual Reregistration bill was a very good illustration of the necessity of the State Society committee members being familiar with the desires of the county society members. He found several years ago that there was a great difference of opinion as to the desirability of the reregistration bill between counties up-State and the New York County Society. He did not know whether they wanted registration yet. It was going to come up this year again. However, he was not talking in favor of it tonight, though he was in favor of it. Dentists and veterinarians had found a similar law very effective in driving out of business fraudulent dental offices and unlicensed veterinarians. There were two objections advanced against this bill. One was that it took away the life-long privilege to practise medicine and made it an annual one. The second was that it charged the medical profession a fee for the protection of the public. The way in which this bill worked was that every registered dentist received a list of dentists registered in the State. If in his neighborhood there was a dentist practising whose name was not on the list, the registered dentist wrote calling attention to the fact that such a name was not listed. The authorities then inquired into the matter and if it was found that the unlisted dentist was practising illegally the Attorney General obtained evidence and prosecuted him. In that way the dentist was protected without any effort on his part and without the aid of the local district attorney. When it came to the health center bill, a statement had been made as the necessity for providing some kind of further care for the sick. If the sick needed further care no one ought to be more anxious to give it than medical men. Dr. Winter said he had gone over some parts of the State, not the extremely rural districts such as Livingston County but the more southern sections of the State, and the conditions were not apparently as bad as it would appear. He had met in consultation a number of men in the more southern parts of the State, many of them county doctors, and he had found the country doctor was a pretty good all-around man. He followed up his cases well, and ordinarily made a very good diagnosis. He was generally very willing to have a consultation if he could get it. The State *Journal* had published a questionnaire relative to the income of doctors throughout the State and it might be noted that in this questionnaire many men were engaged as part time practitioners, which meant that they were specially interested in some particular line of work and that they were more competent in that line to make a diagnosis than the ordinary man. This meant that there were reasonably good consultants to be obtained in the rural districts.

He had found part time specialists in communities of five or six thousand people, communities which were not cities. Automobiles and good roads made it possible to move patients much greater distances than could be done a few years ago. It was very much easier for the rural resident to get in touch with good medical advice than it used to be. Of course if the rural patient lived a considerable distance from a doctor he did not receive as many calls as though he was nearer, but he got along reasonably well as was shown by the fact that the death rate and the morbidity rate of the rural districts was not greater than that of the larger communities. The health center bill would perhaps do certain things to help those districts. The clinic at Goshen last August was an experiment as to the kind of work that would be of advantage in rural communities. Dr. Winter stated that he had attended that clinic, was courteously received, and went over the work that was going on rather more carefully than the ordinary casual visitor would have done. The members of the staff who came to do the work were all good men but they were not better men than those available in the community in which the clinic was held. That brought up the point that Dr. Hunt had made that when a man was selected by the State Health Department it gave him a certain prestige which he did not always deserve above his neighbor who was not so designated. There was some criticism by the local men as to the singling out of these men as a little above the ordinary practitioner. This clinic at Goshen was held for three days. The chemical laboratory equipment was good, but the x-ray equipment was not working. The laboratory examinations were made by a very efficient man. The work done could best be summed up by telling what was reported at the meeting of the Orange County Medical Society in the early part of this month. Three men reported that 90 patients were referred to the clinic with the result that out of the 90, seven received information that was helpful. One case that brought up the statement that Dr. Hunt made, that specialists could be made if they had a sufficiently powerful State organization behind them, was that of a patient suffering from the results of poliomyelitis. He was advised to go to Boston to have a tenotomy done, as though there was no one in New York who could do a tenotomy. So far as the Orange County clinic was concerned many of the men said it was of no service to them. Two men, however, who had sent patients there, had told Dr. Winter that they were satisfied with the returns they got. There was another point in reference to this clinic, that was that the men who attended received twenty-five dollars a day for their services; a good man could scarcely afford to be away from his work for three days for twenty-five dollars. This meant that the medical profession were bearing the expense of these clinics as they were of the clinics in the cities; they were giving time for inadequate compensation. That brought up the point as to how these clinics could be managed. Dr. Winter said it was his experience that the patient in the rural district was getting just as good care as the city patient and if the doctor had laboratory facilities he could make just as good a diagnosis as the city doctor. The difficulty was in following up the cases. There should be a differentiation between actual medical service and social service. To make it clear, if one had a case of epilepsy and treated it, giving bromides, etc., the patient would not get much benefit unless certain rules of hygiene and a régime were laid down. Seeing that this part of the treatment was carried out could be done by a visiting nurse. It was known that cardiac conditions following acute infections of the throat were very common and that over-activity must be avoided. That part of the care was something the nurse could look after. In other words the doctor was too much of a luxury and it cost too much to make a doctor to have him employ his time in doing what the nurse could do. There was here a place for a medico-social plan of supervision and control. If the country districts were given a laboratory and a laboratory technician and if there were public health nurses there would be no need of the State subsidizing the medical profession and it would not be necessary to fix the salaries of medical men. If the physician's salary was sub-

sidized it would keep the right kind of men out of the profession. The doctor would go into the country if he could follow up his work and know what he was doing. As to the chiropractor bill, Dr. Winter said he had one suggestion to make. If they would go ahead and amend the Medical Practice Act so that any man who wanted to could practise provided he passed the same examination as the regular practitioner that would meet the situation. That procedure had eliminated the osteopath. He would not have a specific act against the chiropractors, because if that were done every chiropractor would be licensed who now had his sign out, but an act compelling every one who wished to practise the healing art to pass the same examination would protect against practitioners of this type for all time. The State Society and this Society should get behind a bill of that kind and make it general and not simply against the chiropractor.

Dr. CHETWOOD said he wished to correct the statement that had been made that the Society had not sent representatives to oppose the chiropractor bill. Whenever the Comitia Minora had been notified of hearings they had sent representatives.

GEORGE W. WHITESIDE, Esq., stated that his purpose, in so far as he could do so, was to cover the ground so ably covered by the other speakers, but perhaps from a somewhat different angle. The question was apparently a rural question. We, however, would have to look at it from the viewpoint of the entire State and get away from sectionalism and the political idea. A great deal of poor legislation was enacted for the purpose of trucking to the farmer or laboring man. Legislation of that kind was class legislation, and we must get away from class legislation. The first thing about the health center bill was that it was largely designed to treat the question from the class point of view, though back of it were absolutely sincere motives. At the same time back of the bill was the idea of forcing on the medical profession a combination on their part. The weakness of the medical profession in legislative matters was its inability to function as a whole body. There was too much individual opinion. The practice of medicine had long been a matter of the practice of the individual. It was not like industry where there were combinations and the Government intervened because the combination became almost a superstate. That point had not been reached in medicine. We had not suffered from medical combinations and apparently at the present time such combinations did not exist. The great function of the organization of the State and county medical societies was to permit the expression of judgment of a great profession and to blot out little individual differences. In the health center bill it was proposed that a certain part of the community should be recipients of a certain form of medical assistance not of their own choosing and not precipitated by them, but coming from a governmental source. It might be wise if such a bill came up to show in some way a united front. There were now in operation in large centers group systems of medicine. Whether these could be adapted to the needs of the public he could not say. It would seem that there would be no question of supplying doctors to the up state population if the population was there and doubtless the rural districts would soon be served. It was probable that progress in the development of aeroplane transportation or some other method would provide emergency medical service, and then the health centers now proposed would be obsolete. There had been enough said to awaken the profession to the need of united effort on their part. Very slight reference had been made to the chiropractor bill; he would like to mention that when the matter was before the Governor for consideration there was a train load of physicians who went to Albany. He was along and presented the legal arguments which seemed to be well received. This County Society had registered very effectively. As to the salary plan in connection with the health centers, he thought the last thing the physician wanted was a wage plan in the practice of medicine. They might find it necessary in medicine as it had been found in law to make a change from conditions under which one man did all the work incident to the practice of law to a combination or organization whereby the lawyer em-

employed others to do a great deal of the detail work. Such organizations had been found necessary to meet the demands of a great commercial center. It might be that such organizations might be possible in medicine in which a man might graduate from the position of employee to that of partner. While he scarcely thought this would come, he felt that the medical profession in a few years would be undergoing a radical change from what it was a few years ago. We were becoming accustomed to revolutionary changes, peacefully brought about. Mr. Whiteside suggested that the exercise of police power over the medical profession would have to be watched. The medical profession would have to organize not simply to bring obstructive measures to meet the police powers where they were detrimental to the profession, but for beneficial legislation that would call upon the State to exercise its police powers in behalf of the great public and also not to the detriment of the medical profession.

Dr. DANIEL S. DOUGHERTY defended the Society against the charge of having been neglectful of its duties in regard to legislative matters. He stated that during the past five years no bill affecting the medical profession had gone before the Legislature without the cognizance of the Society. He also explained that Dr. Biggs has misunderstood the purpose of the committee which he said had opposed the reporting of venereal diseases. The purpose of that committee was to oppose the segregation of venereal patients in a hospital under the Board of Health because they did not want these cases taken from the City Hospitals where they offered the most wonderful opportunity in the United States for the study of syphilography. The City Hospitals did not want to lose this department.

Dr. FREDERIC T. SONDERN explained that the reason no representative was present at the hearing on the chiropractor bill to which Dr. Biggs had referred was because Dr. Kevin, who was chairman of the legislative committee, had received reliable information stating that there was no chance of the bill passing, and that it would not be necessary to have representatives there.

Dr. J. MILTON MABBOTT stated that the County Society had also been informed that the chiropractor bill would not be reported out of committee and they were practically promised that it would not be voted on by the Legislature. Dr. Mabbott also objected to the statement that the medical profession never did anything but oppose. He did not see why they should not oppose when they were opposed. He expressed the opinion that the bill which made the osteopath a legal practitioner of medicine was a kind of compromise. It was passed with the consent of the medical societies. It permitted a few men to practise osteopathy in order to keep out hordes because the police power of the State did not prevent them from coming in. The osteopath might manipulate the spine for diphtheria and he knew nothing about antitoxin, yet the people of the great State of New York stood for that sort of medical practice.

Dr. L. W. ZWISCHN also objected to having the medical profession accused of being always obstructionists. It seemed to him that as medical men were legalized to practise medicine and licensed they were entitled to the protection of the State instead of being treated as had too often been the case like a body of criminals. Laws were introduced which were against medical men after the State had given them the privilege to practise and such laws must be opposed. It was not a question whether there were good points or bad points in the health center bill; it was an entering wedge for State medicine. If State medicine was good let us have it but not a wedge. It was no argument in favor of such a bill to say it was going to be passed; they were in duty bound to oppose whatever was against the public welfare. This was only sectional legislation. Were they to pass a law simply for Livingston County? Dr. Winter's suggestion for a general medical practice law to cover all practitioners of medicine met with his approval.

Dr. HENRY S. STARK declared that the health center was simply health insurance in disguise. The financing of health insurance meant the saddling of millions of dollars on the tax-payer and the same was true of the health center idea. It would put untold power into the hands of the State Health Commissioner, which

would not be so objectionable if that health commissioner were Dr. Biggs, but the situation would be serious if the health commissioner was a political doctor, which Dr. Biggs was not. The country physician had certain disadvantages. He was oppressed in that he could not rise to eminence. He grew old in service, as Dr. Biggs had pointed out, but there was a great difference in country practice today from what it once was. In years gone by the patient had to travel long distances to be operated upon; now in every town and in second and third rate cities one found not only good hospitals but good specialists. New York was losing ground as a medical center, and when consultants were wanted they were being sought in other cities. This health center plan was obnoxious not only to the physician but to the population of the rural district. He hoped the Society would go against it.

Dr. HUNT said he had been interested in what he had heard this evening. It was the same thing he had heard all through the State from New York to Buffalo. He thought the keynote was the need of constructive action. If this matter was referred to a small committee of representatives of the Health Department and of the medical profession it might be worked out. There was a great deal to be said *pro* and *con* and it was desirable to steer a "middle of the road" course.

Dr. DELPHEY said a man's point of view depended a great deal upon his position. If he occupied a salaried position he looked at things differently from the man who was dealing with the public. He began to see that because for the last few months he had held a salaried position, but he was still on the side of the medical profession and always would be. He had with him an article which stated that the average physician was 30 years of age before he was able to make a living and it cost \$20,000 from the time a man left high school until he was able to earn his own living in medicine. This represented an investment which should bring in some return and the doctor should not have to fight against measures that if put into effect would reduce his earnings. It was a case of supply and demand and the willingness of the persons needing the supply to pay an adequate sum to supply the demand. Dr. Delphey said he had spent the summer in the northern part of the State and related some personal experiences showing that transportation facilities were such that they enabled a physician to cover a good deal of ground and to do a good deal of work. The objection to reporting tuberculosis and venereal diseases, as he recollected it, was based on the question as to whether it was right for the physician to report what was opprobrious in a patient and whether the reporting of those cases would be a violation of the confidential relationship between physician and patient. Later that difficulty was overcome by reporting cases by initial. It was said that the profession was against everything, but it must be remembered that nearly everything had been against the profession. Dr. Delphey said he had sent out a questionnaire to all the delegates to the State Society outside of New York, and found that there were on an average $2\frac{1}{2}$ hospitals to each county, that three-fourths of the counties had laboratory facilities, and the others reported that they could easily send their specimens to laboratories by parcel post and get reports in a short time. It had been said that this legislation was inevitable and bound to come. They must take the stand that it must *not* pass.

Dr. BIGGS, after expressing his thanks for the confidence shown in the present Commissioner of Health, said one thing was very clear, that was that what they had attempted to do and what the Council thought ought to be done was exactly what the Society was asking for. It was perfectly evident that they could not get doctors in the rural districts unless it was made more attractive for them. As soon as it was better worth while for them to go they would go. This was the reason they had provided that physicians in hospitals and dispensaries should be paid and that a State subsidy should be provided. He believed the physicians in hospitals and dispensaries should be paid. There was no reason why doctors should serve without compensation any more than lawyers or any other class of men should serve without pay. The purpose of this legislation was primarily to make an arrange-

ment whereby physicians should be compensated more adequately. A local community could not do it, so a State grant was provided. He did not regard that as subsidizing the doctors. It was subsidizing the local hospitals so that the doctors serving in those hospitals would be adequately paid. The work the doctor did for the free patient was paid for and the work he did for his own patients was paid for, and he no longer treated the poor patient without compensation. It was simply enabling legislation in that it enabled a community to provide care for its people. He had always believed that there were two things the government owed to its people, one was an elementary education and the other was provision for the preservation of health and the prevention of disease if they could not provide these things for themselves. The State did provide for education and for the care of the sick. The only difference between this plan and Bellevue Hospital and Dispensary was that this plan provided compensation for the physicians who were doing the medical work and Bellevue did not.

Dr. WINTER recalled that Mr. Whiteside had said that the health center bill was not interesting to those who lived in New York City, and begged that they should not believe it. It was of interest to those who lived in New York as well as to those who resided in rural districts. Those living in the rural districts needed the support of the medical profession of New York County.

Mr. WHITESIDE said he merely wished to convey the idea that the up-State men were able to take care of themselves, and to pass a health center bill if they decided they wanted to do so.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held November 10, 1920.

THE PRESIDENT, DR. HERMAN B. ALLYN, IN THE CHAIR.

Symposium: The Doctor and the Drug Addict.

Hospital Experiences with the Drug Addict.—Dr. JOSEPH McIVER of Philadelphia read this paper saying that when the Harrison Antinarcotic Law went into effect a great many drug users applied for admission to the Philadelphia General Hospital. The methods of treatment most generally used were the gradual withdrawal and the Lambert method. In most cases the immediate withdrawal of the drug was not a difficult matter. It was not very difficult to render a drug addict free from symptoms of drug starvation. Nowhere outside of a well regulated institution could a drug addict be kept under the absolute control necessary for treatment. After dismissal at the end of the thirty-day period of treatment it was found that many of the patients returned for another treatment. Experience led to the belief that these people did not desire a cure. Nearly all of the patients had been living in the lowest walks of life and many had had long criminal records. They must have been very weak misfits in life.

Dr. JOSEPH C. DOANE of Philadelphia said that he had been very much interested in hearing Dr. McIver's paper because at the particular time when these experiences were happening Dr. McIver and he had been working together and had then been hopeful of solving the problem in rather short order so far as the Philadelphia Hospital was concerned. Of course their experiences there and his experiences since had been with the second class of drug users, for they recognized that there were two different classes. The members of the criminal class were the ones who found their way into the city hospital, and those in the class with more mental stability were treated in more select institutions or sanatoriums. In the Philadelphia Hospital they had treated in the neighborhood of 3,500 cases; he thought somewhere between 3,400 and 3,500 cases had relapsed since that treatment. Hospital physicians who met this class of patients soon learned the frivolous and playful ways of the drug addict. The average physician who endeavored to treat a drug addict was a great deal more trustful of his patients than he should be. The private physician who endeavored to treat a patient by with-

drawal while the patient was about his work was either a super-physician or a Simple Simon, or he was illegally evading the law, because Dr. Doane did not believe it could be done successfully.

The Psychology of Drug Addiction.—Dr. JOHN H. W. RHEIN of Philadelphia read this paper, saying that any effort to correct the evils of drug addiction must be based upon a thorough understanding of the psychological factors underlying the cause. He did not believe that mental deficiency was a cause of drug addiction, nor did he believe that the proportion of mental defectives was very high among drug addicts. He believed that improper prescribing of opium, morphine, or heroine by physicians, while responsible in some degree, was only incidental in drug addiction. He meant by this that the cause of development of the habit was inherent in the individual. The drug addict was a psychopath before he acquired the habit. He was a person who could not face, unassisted, painful situations, he resented suffering physical, mental, or moral; he had not adjusted himself to his emotional reactions. The most common symptom which required relief was a feeling of inadequacy, inability to cope with difficulties. These conditions called for an easy and rapid method of relief which was found in the use of drugs. It was simple enough to cure the victim of his craving temporarily, but the difficulty was in preventing a return to the habit. To cure a drug addict meant to reconstruct and reeducate his personality so that he could adapt himself to his emotional reactions.

The Scope of Therapeutics in the Relief of Narcotism.—Dr. ALEXANDER LAMBERT of New York City read this paper in which he said that the real therapeutic care of the patients was only begun when, successfully unpoisoned from his particular narcotic, he was being built up and regenerated in body and mind. Treatment must vary not only with the kind of narcotic taken, but, to a certain degree, with the amount and length of time it had been indulged in; also, with the cause which prompted the choice of narcotic. Some plan of unpoisoning a patient was an absolute essential. The principles of the belladonna treatment were the reduction of the narcotic in a few days during which there was given hourly day and night a mixture of belladonna, hyoscyamine, and xanthoxylon up to the physiological limit of belladonna with vigorous catharsis during the treatment. After four or five days the patient no longer craved the drug. The eserine and pilocarpine method he had found very useful in heroine addicts. Ambulatory self-education in the majority of patients was a dishonest and useless method doomed to certain failure. It was the method under which the trafficking and disreputable physician cloaked his practice. Its hopelessness and uselessness should be universally appreciated and condemned. The great public health problems of narcotism were today centered around the cocaine and heroine addicts who constituted nearly four-fifths of the addicts. This was the group whose personalities were not adequate, the result being that they offered a grave social problem. In treating the narcotic patient it must always be remembered that the morbid process was a functional poisoning resulting in perversion of the functions. To be successful one must recognize these various perversions and nervous inhibitions.

Dr. HOBART A. HARE of Philadelphia said that the Society was exceedingly fortunate to have gotten Dr. Lambert to read his paper because in the majority of instances, papers of this kind were read by neurologists or psychologists who did not look at patients in the way the humble general practitioners were prone to observe them. It had also been fortunate because all the profession knew that Dr. Lambert had been peculiarly and particularly interested in this class of patients and because he had devised methods of treatment which were to a large extent his own and which had given large bodies of people much benefit. He had frequently used the hyoscyne treatment and he believed it was the most valuable in the case of the morphine habitué. He knew of nothing which approximated it. In his experience the patient could be made perfectly comfortable. In his comparatively limited experience in these cases there were two classes: first, the fundamentally rotten by inheritance,

and, second, those men and women, like anyone of us, who through illness had gotten to be dependent upon morphine, codeine, or possibly even heroine. These people were easily cured. They separated themselves from the true morphine habitué, who said, "Doctor, for God's sake save me!" and did not mean it. These people said: "Doctor, I am not going to take any more of that narcotic," and they meant it. There was a difference in the morale and courage of the two classes. Twenty years ago he did not have much faith in the cure of any case of morphinism. Increasing experience had taught him that there were many persons, men and women, men who had had prolonged bladder trouble, or women who had had prolonged pelvic trouble and had gradually slipped into the habit of using these drugs. With a little care and help they could be made to emerge from their difficult position. He said he would like to utter a protest against part of the campaign which was being carried on against narcotic drugs. He thought we had all come to the conclusion that a large number of people were being deprived of relief from hypnotics by the crusade which was being made to save a whole lot of "rotters," whose death would be a relief both to themselves and to their relatives. Recently he had received a letter from the Treasury Department in reference to a bill to be introduced into Congress to wipe heroine off the map, and to forbid its importation into the United States. He had written back that there was a danger of depriving the medical profession in its struggle with misery and disease of a valuable drug. For every individual saved from the heroine habit there would be thousands of honest souls deprived of it. In some cases with a cough, heroine acted without producing disagreeable side symptoms that the other derivatives of opium would cause. Heroine would do it without any of the nausea and depression that morphine produced. He used very little in the way of narcotic drugs, but if Uncle Sam passed a law forbidding the importation of heroine he would see that he was stocked up with enough heroine to last his lifetime, not for himself but for his patients. Many physicians of his acquaintance considered heroine one of their most useful drugs. The very fact that it was abused by the degenerate was a sign that it had power for good when prescribed by the physician for the patient who really needed it. In postoperative conditions it was a very valuable nervous sedative.

Dr. JAMES M. ANDERS of Philadelphia said that to his mind the subject of the therapeutic treatment of drug addiction was an important one. Practically all of the advances made in our knowledge of this subject, in the last decade at least, had come from Dr. Lambert. It seemed to him that opium was often used, as Dr. Lambert intimated, for the purpose of fortifying the personality when about to face some painful or unusual situation. He had known a physician, a prominent member of the medical profession, who invariably, before addressing a large body, which he had been in the habit of doing, would resort to a dose of heroine. He knew of other instances in which this had been done. He had also resorted to hyoscyne as a method of treatment in these cases, but had not found it quite so satisfactory as Dr. Hare seemed to have done and for the reason that it did, very often at least, seem to upset the patient mentally and to a disturbing degree. The withdrawal phenomena had been produced in normal animals by the injection of the serum of the blood of a tolerant person or animal. If this were true, then it seemed to him that active elimination of the drug by means of vigorous purgation must constitute an important element of the treatment. He would have liked to have heard more about the particular physiological effect of these remedies, as to the basis for the use, for example, of belladonna. We knew that the chief physiological action of belladonna was to depress the sensory filaments and he was inclined, or rather tempted, to ask Dr. Lambert whether the use of belladonna was based upon this physiological effect of the drug. When about ten years ago Dr. Lambert published his special method of treatment of these cases, the speaker had thought it rather heroic, and he had not accepted it immediately; but about five years ago he had had

under his care a lady of high social position, who was an alcoholic addict and he had made very little headway and finally decided to send her for treatment to New York City. She went and obtained a cure and about the same time he learned of a couple of morphine habitués who had been confirmed cases, who had also been cured at the same place. He had looked into it and believed it to be the most effective method of which we had any knowledge.

Miss SARA GRAHAM MULHALL of New York City said that heroine had been only 9 years in this country and during that brief period of its existence it had reached the most tremendous magnitude in the habit of drug addiction. In New York State 95 per cent. of the addicts were heroine addicts. There was being manufactured and imported into this country more heroine than in any other country in the world. She wanted to impress her hearers that it was the most baneful drug that the medical profession had in its Pharmacopeia.

Dr. THOMAS S. BLAIR of Harrisburg said that there were literally thousands of doctors who had stopped the use of heroine. The year 1919 had shown a per capita usage of physicians in Pennsylvania dispensing heroine approaching about 16 grains a year—a little less than that. He thought he was justified in saying (although the 1920 report was not out) that the per capita would hardly go over two grains a year for 1920. Philadelphia used the larger proportion in the State of Pennsylvania, closely followed by Lancaster, Oil City, and Reading. The city of Pittsburgh used very little. They did not have the trouble with heroine addiction in Pennsylvania that they had in New York City. Three heroine addicts in Philadelphia were using today more of the drug than all the public hospitals of Philadelphia used in 1919. Consequently he was justified in saying that the professional usage of heroine in the State of Pennsylvania was not 1 per cent. of the total use of the drug. There were two things he could say from official records: Cocaine was going out with the dentists, who were not using it, but were using procain; heroine was going out with the doctors.

Experiences in the Control of Drug Addiction in New York State.—Miss SARA GRAHAM MULHALL, First Deputy Commissioner, Department of Narcotic Drug Control, State of New York, New York City, read this paper saying that when she took office in April, 1919, prescriptions for 40 to 90 grains of morphine or heroine were frequent; now it was exceptional to find prescriptions for more than 10 grains of morphine; cocaine had been restricted to a few grains per month and heroine had been practically eliminated. A clinic and a hospital had been established for handling drug addicts but experience had proved that both these had resulted in failure. The hospital had provided for a six-weeks course of treatment; about one-third of the addicts of New York had passed through but the majority had relapsed. In spite of the failure of the clinic and the short-term hospital, they had served a useful purpose in pointing the way to the only possible solution of drug addiction, that was, the Colony Plan for the rehabilitation of the addict physically, mentally, and morally.

Present and Contemplated State Legislation, Relative to Drug Addiction.—Dr. THOMAS S. BLAIR of Harrisburg, Chief of the Bureau of Drug Control, State of Pennsylvania, read this paper in which he said that it was evident that largely unnecessary supplies of narcotics were coming into the country. The 1919 report of the Bureau of Drug Control of Pennsylvania had shown that the per capita coming into this State through legitimate channels, figuring all educts on the basis of opium, had been 24 grains a year. The average consumption in public hospitals had been only 3 grains per year. Thus it was seen that legislation was needed to curb this menace; this should be national in scope. Any State laws should be cooperative in nature. From the point of view of the Internal Revenue office the Harrison Act was a very good piece of legislation, but, from the point of view of the physician, druggist, dentist, and veterinarian and those concerned in its enforcement it was insufficient. It entailed a great degree of annoyance and book-keeping upon professional persons. If the distribution of these

drugs was placed in the hands of the U. S. Public Health Service, a large amount of this would be unnecessary. The narcotic law of Pennsylvania needed revision in such a way as to increase the police power. A large tract of land had been purchased by the State to be used in the establishment of an institution for the treatment of drug addicts, but that was as far as the matter had gone. A survey of what had been done in this direction by the various States in the way of institution treatment of drug and alcohol addicts showed that in practically every case such efforts had resulted in failure. The reason for this had been chiefly that the patients, on discharge, reverted to their old habits. Therefore, there was little encouragement to open such an establishment.

Dr. ALEXANDER LAMBERT of New York City said that one thing which struck him was that each one was talking about the group with which he was most familiar and had had most to do with. He thought that there was no question that Dr. Doane and Dr. McIver were correct as to the ordinary hospital rounder of hardened habit. One dealt there with the low grade in which life was not worth living without some form of drug to help their labor and their joys; without it they insisted that life was not worth while. It was almost impossible to do anything with that group. The other group, the morphine habitués suffering pain, were anxious to get off and they stayed off. They were not generally known as such and they were only too anxious to be rid of their addiction. There must be a different kind of cough in Philadelphia—the one spoken of by Dr. Hare. He had not yet seen it in New York and he thought it would be worth investigating. He thought that with greater investigation on Dr. Hare's part he would come to the same conclusion that the rest of us had who had suffered from the waste of time struggling with the heroine habit. Heroine was an unmitigated curse. One could do just as much without it; and the patient would get over his cough in the end just as well. What was the physiological action of belladonna? So far as he could watch it, it was a cutting off of the exaggerated action of the extended vagus in general. It was a curious fact that when one was giving belladonna in the early stages the pulse became slower and slower; that, one would say, was not cutting off the vagal endings of the heart. But there was some other action there that slowed the vagus. The diarrhea of sudden cutting off was prevented. That was his own theory and, like all theories, was subject to change without notice on the accumulation of new facts.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

HOOKWORM AND MALARIA RESEARCH IN MALAYA, JAVA, AND THE FIJI ISLANDS. Report of Uncinariasis Commission to the Orient. 191 pages with illustrations. Published by the Rockefeller Foundation International Health Board.

THE ROCKEFELLER FOUNDATION INTERNATIONAL HEALTH BOARD, Sixth Annual Report. 210 pages with illustrations.

THE EYESIGHT OF SCHOOL CHILDREN, Bulletin 1919, No. 65. By J. H. BERKOWITZ. 128 pages with illustrations. Washington Government Printing Office.

NATIONAL HEALTH INSURANCE AND THE MEDICAL PROFESSION. By FREDERICK L. HOFFMAN, M.D. 122 pages.

CORNELL UNIVERSITY MEDICAL BULLETIN, Vol. X, No. 1, July, 1920. Illustrated. Published by Cornell University.

PROGRAM OF THE CENTENARY CELEBRATION IN HONOR OF THE BIRTHDAY OF ELISHA KENT KANE under the auspices of Kane Lodge.

THE ORGANIC EFFECTS OF REPEATED BODILY ROTATION. By COLEMAN R. GRIFFITH. 125 pages.

Miscellany.

The Strange Existence of the Abbé de Choisy.—This distinguished ecclesiastic who was at one time Dean of the French Academy is now believed to have been a badly disequibrated individual. He was born in Paris in 1644 and died in 1724. He was brought up by his mother with extreme care in the aim of making him a courtier. For some reason which does not appear she dressed him as a girl during his early childhood. He decided to enter the Church at the age of 18, and was promptly appointed Abbot to a priory in Bourgogne; but he soon left his charge and claims to have devoted five months to the assumption of female rôles in a Bordeaux theatre without any recognition of his sex. His mother died when he was 22 and he gave his portion of the estate to his brothers, although retaining the jewels which appeared to be of the kind worn by women, such as ear-rings.

He must, however, have had an independent fortune, for he is spoken of as very wealthy. He bought a house in Paris in a rather plebeian neighborhood, so that he could dress as he pleased. He secured an extensive female wardrobe and went by the name of Mme. de Sancy, and he gave various grand entertainments during which no one suspected his sex. There were two sisters who lived adjoining him and he fell in love with one and married her, the girl being dressed as a boy and called M. de Maulny. But a plain citizen having fallen in love with the young lady de Choisy gave her up.

The King finally got wind of the abbé's strange life and ordered him to leave his house for his home in Luxembourg. He later appeared at Bourges as a countess. His chief end in life seemed to have been to fall in love with some young girl and give her a boy's name. When the latter had an offer of marriage, de Choisy never seems to have objected. After a serious illness he decided to resume his existence as a churchman and led a most exemplary life full of honors, one, as stated, being Dean of the Academy. His personality is a most puzzling one for while a transvestite, there seems to have been no real homosexuality. He fell in love with young women in a normal fashion although he liked the suggestion of masculinity about them. He revealed himself to some of the young women and in the case of one Rosalie she bore a child which de Choisy adopted. There is therefore no doubt that sexually he was normal and he had no friendships or companions among men. The transvestitism was due to mixed factors apparently. He became accustomed to female apparel at an early age and seems to have greatly enjoyed deceiving people as to his sex. He enjoyed wearing beautiful clothes and many jewels and could do this best as a woman. That he could change this penchant almost instantly and never return to it showed the absence of a feminine psyche. In his old age, after his retirement from all public activities, he sometimes wore female articles of clothing, but it is suggested by the author of this biographical sketch that this was done in penance for the errors of his youth.—*Le Progrès Médical*, December 11, 1920, xlviii, 50.

THE CONVALESCENT TREATMENT OF HEART DISEASE BY EXERCISE APPLIED THROUGH NATURAL WORK AND PLAY METHODS.

By FREDERIC BRUSH, M.D.,

WHITE PLAINS, N. Y.

MEDICAL DIRECTOR, THE BURKE FOUNDATION.

(Study made through the F. K. Sturgis Research Fund.)

THIS paper reports upon an experience with 2,500 cases of valvular heart disease treated alongside of other patients in a Free Convalescent Institution of 300 beds from April 1, 1915, to July 1, 1920. Records of 1,000 of these cases, in two groups representative of the earlier and later methods, are especially studied.

A brief description of the institutional plant is essential for fair interpretation of the procedures and results. The sixty-acre grounds rise 100 ft. (to altitude of 300 ft. above sea level) from front to rear and contain forest, lawn, meadow, and farm gardens. The widely extended two- and three-story buildings are upon a terrace in the center. Hard surfaced, highly crowned roads and walks, usable in all seasons, total two miles in length and are mainly in grades of from 2 to 7 per cent. Outdoor games equipment comprises one regulation baseball diamond and one with 60-ft. bases and a special catcher's cage for cardiac boys; four short golf courses, one long course, three tennis courts, hand, basket, volley, and tether ball, Badminton, Rugby and soccer goals; six croquet courts, lawn bowls, quoits, discus, 5 to 12-lb. shot put and 10-lb. hammer throw. Swings, settees, and hammocks are widely placed to give destination to and rest after walks. Concrete dance and play terraces serve important ends.

Indoors are all feasible games, especially those inducing mild exercise, as pool and billiards, ring-toss, music and dance facilities in each section, with central assembly hall, extensive occupation-therapy rooms, etc.

ADMISSION STANDARDS FOR HEART DISEASE.—Patients are selected by our City Admission Office from proposals now made mainly through the Special Cardiac Clinics. Improving results are constantly following these more careful selection methods. Heart patients are limited to 80 beds (for medical and administrative reasons). The type of heart patient chosen for this treatment is indicated by the question: Has the proposed applicant sufficient heart and general reserve to be repairable, rehabilitable, up to full or handicapped wage-earning,

homekeeping, schooling, in a few weeks' term of rest-work-play-exercise treatment in the country?

The ideal person for this treatment is under 45 years of age, has suffered but one or two heart failures requiring bed care, has recently been well diagnosed, rested, and graduated into moderate physical exercise equivalent to walking 20 minutes on the level or climbing slowly two flights of stairs having a 20-ft. rise with slight if any dyspnea or discomfort, and who is temperamentally qualified for this reconstructive plan. A few others outside of this classification are occasionally entered, as for beginning heart overstrain and "potential" heart disease (prevention). The economic and social bearings are carefully estimated in each case. The special card of entrance, record and "follow" gives condensed details of the admission procedure and is depicted below.

ASSOCIATION OF CARDIAC CLINICS

From Clinic of		Hospital

Routine at the Institution.—The physically and

nervously trying admission day (in process from early morning until 3 p. m.) gives a valuable test of the patient's reserve and adaptability, and upon arrival in the country after a 25-mile motor-bus ride they are inspected by the Resident Physician, with card-history in hand, and a few notes made for the house-card, especially for those showing unusual exhaustion or poor physical or mental condition, and directions given as to certain placement in relation to stairs and associates, immediate bed-rest, watchfulness, etc. In cottage quarters coffee and crackers are served and a brief group talk given by the head nurse, encouraging to full co-operation and to early abeyance of the very prevalent doubts and fears, as of stair climbing and other exercise. Reclining or bed-rest follows. Wheel chairs are generally refused new patients, who must walk to the dining room, 200 yds. After supper many will be found strolling about the slopes, watching the games, dances, etc. The contagion of normality is already at work.

The average day of a typically progressing male patient in the third week may well be sketched: Rise at 6.30, no bathing requirements; sit outdoors or walk, breakfast at 7.30; make bed and tidy room; morning papers, smoke (no restrictions upon this), brag and argue world problems, wash and repair own clothing, go to store, library, or barber shop; play games outdoors and in; obligatory medicine ball, etc.; take supervised walks on the grades; glass of milk at 10, prescribed occupation 10.20 to 11.30; rest, dinner at 12.30; "rest-hour" 1 to 2, flat on bed with no talk (longer for weaker ones); play in or watch outdoor sports and tournaments, walk to village a mile away or do a few hours of work on farm or buildings (for a half-wage); supper at 5, rest, walk, or games, read or write letters, dance; bed and lights out at 9. No special night supervision of cardiacs has ever been indicated.

The above in general applies fairly also to women and girls, excepting that they play games less and dance, sing, and laugh more. Boys' exercising is more largely recreational and theirs is the only group of the four which does not require much forcing in this. Disinclination after early middle age to other than wage-work exercise (on account of mental and physical inertia) handicaps convalescent upbuilding and is constantly sought to be overcome by more youthful leadership and example.

Medical Supervision.—The Resident Physician, with nurse, meets each patient alone on the morning after arrival and makes examination, of uncovered chest in most cases, sufficient to order in writing the occupational exercise to begin that day or a week or two later, designating its kind in general only, as "sitting," "light," "full outdoors," etc. Marked cases of malnutrition are given extra milk and olive oil. Overweight (to be noted later) is particularly discussed with the patient. Mental, racial, and habit peculiarities are met with adjustment-suggestions which impart new hope and a beginning-understanding of the effort-cooperation desired. Mental therapy and the suggestion therapy of environmental example are most important to this class. Patients are examined medically a week later, and less frequently as they show good progress, until the final conference for discharge.

Almost no drugs are used. The laxative habit is insistently broken up; practically no special dieting is afforded. Many of the cardiacs have become border-psychopaths. Too much treatment and too many restrictions have played no small part in furthering this mental condition, and this anti-drug and anti-treatment method is of great complementing value in overcoming this abnormal outlook. "Go to bed and skip one meal" is the usual advice for the many minor complaints. It is generally not followed fully and thus it becomes a test and a correction of attitude. Hydro and like physical therapies are avoided.

Digitalis in small dosage has been tried with the weaker hearts and mainly discarded because of inability to appraise advantages from its use in comparison with control cases receiving no drug. Digitalis has been most used in auricular fibrillation, but others of this class have done equally well without it. Insomnia is not treated with drugs and is little complained of after the second week.

FORMS AND APPLICATION OF EXERCISE.—As best fitting our diverse age and diagnosis grouping, it was decided at our opening in April, 1915, to begin a broad experiment in the exercise treatment of selected patients with chronic valvular heart disease, using as the essential means only work, play, and what have been termed "normal life methods"—adapted to an institutional regime. The various gymnastic exercises are not considered as unfeasible nor unsuccessful in the convalescent treatment of heart disease and they may be added here, with the younger patients.

Nearly all of our heart patients come with marked disinclination to exercise, amounting frequently to fear or obsession. This attitude follows the customary composite of physical prohibitions (don'ts and can'ts) as fostered by physicians, hospitals, schools, and parents. Hence our attractive and agreeable forms of exercise prove of distinctive value in overcoming this inertia.

These heart patients are directed to begin at once to play croquet, short-golf, quoits, soccer practice, coasting and snow sports in season, volley ball, tether ball, short trial dancing, group games upon the green, and ball-play (light practice). After a few days of cooperation they will be found indulging more actively and, if young, to have entered upon light tennis and modified baseball and soccer. Certain of these games merit description.

Golf for eight months is the best adapted of all games and most generally used. The courses are laid close to the cottage steps, upon slopes varying from 2 per cent. to steep banks of 20 per cent. grade, and arranged up and down to induce much grade walking (without consciousness of a set task). Holes are from 10 to 50 yds. in length and the stroke is at most but "short approaching." A staff links of full-shot holes is also used somewhat by advanced patients, by invitation. Nearly all classes enjoy this unique modification of the game (called "short-golf") though it is new to most of them. Weekly prize tournaments with mixed sex and age groupings help to maintain interest.

Croquet is frequently set upon gentle slopes. The bending and posturing in this, as in quoits (much played), and the "weights," induce appropriate heart exercise. Boys and a few men play hand-

ball moderately, but cardiacs, with a few exceptions, are barred from the cottage competitions in this sport.

Tennis amounts merely to mild practice exercise and is considerably played by girls and young women. *Badminton* is increasingly used.

Dancing (outdoors in summer) ranks high as physical and mental therapy. The majority come firmly instructed and opinionated *not to dance*, but it is insistently prescribed. The middle and older ages often join or practice it in their cottages. The dance period is one hour three or more times a week, and is supervised. It is easy dancing, with many rests, and often interspersed with other entertainment. Contra-dances are encouraged. Some patients, after attaining good cardiac reserve strength, have given fancy dances of considerable activity and duration. Only about a dozen instances can be recalled in which patients (young women always) have left the floor in distress and the weakness was but temporary in each case and partly hysterical. A *dancing class* for boys and girls is conducted during the winter, instructed by older cardiac patients.

Ball play comes naturally to all and may be most readily utilized. Footballs kept outside are bound to be kicked—and kicked back. The exercise limits itself and is excellent. Hollow rubber, golf, and soft playground balls are freely issued and their bouncing, batting, toss-catch, and chasing (both sexes) afford no small amount of muscle and nerve training.

Baseball is veritably "in the blood" of the American male. "What! Can I play ball again?" is the query. Eyes brighten and fingers work in the palms. "Yes," is the answer, "you are to play ball. Practise lightly at first, then get written baseball permit from the physician and begin cautiously 'in the field', or at first base, have a runner when you bat, or stop after making one base. Do not pitch nor catch (exceptions made). Drop out and give others a chance. Be a 'fan' and noisy." This game for cardiacs is to be understood as a modified one as it is played in the convalescent group and not as swift, tense, first-class baseball. Much of it is casual, about the lawns. It comprises short runs and quick, brief uses of every part of the body, aggregate long rests, arguments, badinage, thrills, the inspiration of audience. A six-innings' limit to set games is often made.

A *field-day* program in which heart patients compete for prizes with others illustrates the extent to which vigorous brief exertions are encouraged; for men, 50-yd. dash, throwing baseball, 10-lb. shot-put, 10-lb. hammer throw, discus, potato race, etc., with like suitable, easier contests for women and girls. Various lawn and cottage group games are, of course, constantly improvised; while the romping, wrestling, tree-climbing exercises of the children are perhaps best of all.

Stair-climbing (from one to three flights) several times daily has proven not only safe but a beneficial form of graduated exercise, patients being instructed as to the rests, at first, on landings, etc. Stair-fear is almost an educated obsession, and to be measurably overcome. The experiment has been repeatedly made of moving a patient, who thought stairs were detrimental, to a ground floor

room and later back again without appreciable effect upon progress.

Certain unclassifiable exercises require mention only, such as the activities of cottage care, singing, music, and entertainment, personal hygiene and upkeep and improvised play and work (not inconsiderable).

Walking, though of high intrinsic value, has proven a partial disappointment because it has not been done enough. Evidently it will be necessary to give more supervision of groups and individuals to gain the maximum of benefit therefrom. All are told to walk increasingly on the graded fields and paths to the point of moderate, transient dyspnea, outside road hikes are conducted with much benefit. A standard question of the examiner has come to be: "Can you take the 'gate-walk' ($\frac{1}{4}$ mile of 4 to 6 per cent. grade) with fair speed and without shortness of breath, pain, or other discomfort?" An affirmative answer is given considerable weight in prescribing more exercise or as evidence of fitness for discharge.

Occupational Exercise.—After from one to ten days of observation and lighter routine activity, work-therapy of about $1\frac{1}{2}$ hours a day is begun. It consists of the usual basketry, cement, painting, carpentry, repairing, sewing, art-work, etc., in the shops, while outside and about the buildings grounds-cleaning, grading, planting and upkeep, forestry, athletic field care, haymaking, gardening and vegetable preparation, path building, snow shoveling, etc., afford wide variety in strengthening and heartening occupations. Watchfulness by overseers discovers those few who early tire or misfit and readjusts them as to time and placing, after a medical conference if thought necessary. There are many atypical positions of exercise value, such as mail handling, policing and leadership, errands, office and various other assistantships, which are preferably given to those needing encouragement and holding to the persistent cooperation required (personal influence therapy).

A *cycle of work-cure*, as accomplished in about 15 per cent. of our cases, is as follows: (1) one hour plus daily in sitting shop or other light work; (2) outdoor occupation or leadership up to two hours plus daily; (3) engagement as "patient-assistant" for from three to six hours daily on a handicapped wage; (4) full employment about the institution (or in neighboring places) with discharge to help-quarters, but retention of medical oversight. Return to former city employment (modified) or to new placement also completes the cycle appropriately. This is ideal grading through work from semi-invalidism into normal (cardiac) life, and in its consummation mental and play-therapy have ever a large part.

CRITERIA FOR DETERMINING THE KIND AND AMOUNT OF EXERCISE.—To test the cardiac reserve power by observation of the patient in physical work and play, and to increase that power by gradually augmented work and play exercise have been the plans from the beginning, and their safety and value were early in evidence. No use has here been made of the technical tests of cardiac efficiency and reserve. The reaction to exercise in heart disease has been determinable in our experience only by trial. Special advices of sending physicians have

in the past proven often of negative value; and even now, under fairly complete cooperation and organization, patients are frequently referred with various unfortunate prohibitions, such as to exercise "little" or "none." The difficulty of overcoming the ingrained inertia in such cases may be inferred.

Rapid or irregular pulse, cyanosis, dyspnea while sitting or in moderate room-movements, pronounced anemia, subacute rheumatic or other infection foci, signs of lung congestion, or cardiac asthma, and general muscular and nerve weakness with malnutrition, determine the prescription for postponed or lighter exercises and careful checking of progress.

No instance of definite relapse with decompensation attributable to the exercises has been recorded. A considerable number complain at first that this or that game, work, or stairs are "too much for them" (causing fatigue, dyspnea, heart-pain, faintness, etc.). They are studied and usually put back with encouragement to the same (or slightly modified) activities, and succeed therein. The psychoneurotic element has grown large in so many of them that insistence upon a regime is essential to their restoration.

Little significance is given to the *different valvular lesions*, excepting to aortic insufficiency, which seems thus far to require slower gradation in exercise and to have presented somewhat less successful end-results. Fibrillation has not been present in a sufficient number to justify broad judgment thereon.

Rarely a slight heart overstrain is noted—and almost invariably in male youths of "nervous" type. Attendants are instructed to watch for persisting dyspnea, unusual pallor, spot-congestion of cheeks, and marked tiredness or languor—and to take pulse at times. Youths go through the early periods of ball or other play or work with pulse up to 115 (or briefly much higher) but of good quality and this is not considered prohibitive. The characteristic facies (anxiety-pallor) is the most important of these observation tests. To those showing some heart overtaxing the first advice is: "Lie down a bit nearby." To bed for a few hours with ice application and a mild opiate follow, if necessary. Watchfulness for 48 hours assures absence of delayed fatigue effects, and steady improvement for weeks after, with gradation into wage-work, answer, in part, the criticism that we have no measure of the possible or probable later unfavorable results of this, as compared with the prolonged rest-treatment.

Prolongation of the physical effort evidently carries the main factor of danger. Brief exertion with frequent pauses acts favorably, which suggests conditions to be sought in regular employment. Continued hand lawn-mowing, tamping, carrying weights, or wheeling loads to distances have proven too trying in many cases, or until later in convalescence. "Pitching" in baseball needs time-limiting and watching; circling the bases (120 yds.) proved definite overdoing, while the 50 and 75 yd. dashes are taken successfully. Two cardiacs playing handball may show overstrain while four together do not (more rests); the "gate-walk" taken steadily may overtire, while with two brief pauses it can be accomplished comfortably against the wind. Two or three men alternate successfully

upon our lawn-mowers. Many patients think (told?) that they can not do bending or stooping exercises and occupations, but they can.

It is interesting to note that there is a general belief among those attending these patients that *mental and emotional stresses* have been causative factors in several of the overstrains and serious relapses. A careful search would probably have revealed obscure reinfections in some of these cases, yet the question seems deserving of further study. For example, a high-strung boy, progressing well in exercise, collapsed into a three-day bed care requirement (moderate insufficiency—pain, tachycardia, dyspnea, etc.) while much excited over being "tied" in a 5-lb. shot-put contest before an audience, though engaged in only two puts at the last with long rests and a history of having done much more with the shot on previous occasions. Probably the mental and nerve stresses upon two only in hand-ball, as against four with their word play and lack of personal contest feeling, differently affect heart action. A woman decompensated badly from an apparently excellent condition in part-wage work the day following serious (to her) accusations, investigations, etc. Umpiring a much disputed ball game set back badly a youth who had gained, before and after, in playing baseball. Instances are recalled of the lesser degree relapses immediately after quarrels, domestic upsets, "bad news," etc. No evidences of infection or of physical overstrain were determined in these persons, who were notably of hypersensitive organization. Heart weakening reported in a number of cases in the first week of return to the city may be in part due to other than physical stresses.

Relapses with insufficiency requiring return to hospital care, as recorded in tables appended, have in no instance been credited, after reasonably painstaking investigation, to overstrain from the exercises. Delayed fatigue effects, though not noted, may have been factors, the only measure of these being the observed "general condition" of the patients. Notably nearly all of these "breaks" came "out of a clear sky," no immediate causes being discovered. Exceptions were with the mental stresses, as noted above, and in cardiac asthma and bronchitis, in which the deterioration was measurable. This is in line with others' experience and is significant in suggesting *more courageous persistence in appropriate exercise* (work and play and gymnastics) and caution in accepting the conventionally ascribed causes of acute heart failure.

RESULTS, DISCHARGE, AND FOLLOW UP.—The successful country convalescent exercise treatment may be typified in a young man who arrives weak, anemic, depressed, and fearful of exertion, who grades through light occupation-therapy and sports to from three to five hours of subnormal work and play per day from the third to the sixth week, who then enters short-hour physical wage-work or increases play and occupation until he comes in on the sixth to eighth week clear eyed, well conditioned, undyspneic, with ambitious request to be allowed to go back to his regular work or to seek new and better fitted employment (provided for by special cardiac-placement agencies). Follow care is then given, for years after even, by heart clinics, social service departments, employment bureau, etc.; and

he may be sent back to the country institution at times when evidently overtiring, for *preventive recuperation of from two to four weeks*.

Tests of Good Progress.—These are ability to exercise increasingly without signs of heart and general overstrain, desire to exercise and to broaden routine toward normality, improvement of anemia, musculature, posture, and facies (the latter of much significance) and improved heart condition and functioning, as estimated also by standard physical examination. (Heart examinations are made as infrequently as possible for mental attitude reasons.)

Weight gain of moderate degree is in the main desirable as confirming good condition, but large gains are generally incompatible with the exercise strengthening method. *Weight loss* has been studied here and found (with few exceptions, such as with infections) to have been salutary, many heart patients being overweight from prescribed under exercise and invalid forced feeding.

Those exercising most (the cooperators, the "triers," as we have come to call them) *get best results*. Many of these have greater cardiac reserve power to begin with, no doubt. The slow gains and partial failures occur with those who through fear, obstinacy, or constitutional unfitness persist in the attitude of physical inertia with its usual accompanying border-neurasthenia. Many young men with only mild heart defects have become athletically feminized. The unresponsive are held to a fair trial only and discharged as unsuited to the methods.

More women than men are found in this latter classification, women having an average narrower background of inherent and habituated physical play and work to build upon, less of inspiring forward-look to ambitious occupations, and somewhat more persistence in the temperamental depressions and obstacles. The treatment is measurably *less successful with women*, but this may be offset in reconstructive values by the fact of their considerably lower physical requirements for after life. Girls up to fourteen or fifteen are only a little less responsive than boys.

THE INCIDENCE OF INFECTIONS AND THE DEATHS DURING RESIDENCE.—That the exercises, coupled with the other upbuilding elements of country convalescence, develop augmented resistance to the various infections is a rather general belief which is supported by a special study made of the 400 cases (men, women, and children) under treatment from May, 1919, to July, 1920 (see tables), carrying through the winter season of the second severe influenza epidemic and passed by these patients in an institutional atmosphere with hundreds of others variously ill. Their records show no incidence of influenza, pneumonia, pleurisy, acute or subacute rheumatism, acute endocarditis, or chorea. There are recorded but seven attacks of tonsillitis (follicular and all but one in children) and but fourteen of "colds" with moderate bronchitis, mostly in ages 16 to 35, considered to be worthy of reporting to the resident physician. Many transient "colds," recurrent pleuritic pains, etc., occurred, mainly during the winter months. Some nocturnal cough was noted, disappearing with the second week's improvement. But three patients out of the 2,500 are known to have had true anginal attacks here.

The six deaths within the institution among the 1,000 heart patients under special survey were all in men between the ages of 40 and 50 with aortic lesions, and occurred in the second or third week of residence. In five, acute heart failure came on rather rapidly and without discoverable inciting cause. All had been on light exercise only and were apparently improving slowly. The other man had been mainly resting for seventeen days because of poor compensation and brought on the fatal illness by a 24-hour trip to the city against the advice of physicians. A few others of the 12 sent back as uncompensated to hospitals are known to have died later in that illness.

TABULATIONS AND STATISTICS.—One thousand cases have been chosen for review as to progress in convalescence, and to some extent in after competitive life. The early group of 600 first treated comprised many faulty selections (uncompensated and otherwise unfitted); the latter 400 have come under improved organization, including selection, preparation, treatment, occupational and educational placement, and follow-care.

In 1917 a study was made of the first 600 cases under care during the two years preceding. Of these cases 130 were in boys from 10 to 16 years of age and 470 were in adults of both sexes and of various ages.

The boys were quartered on a large farm apart from adult patients but mixed with three-fourths non-cardiac boy convalescents. The supervision was never close, there was but little shop-occupation; mid-day rest hours, etc., were rarely kept, the equipment was essentially only the "old farm" on which they "ran free," yet it is noteworthy that the results with these 130 cardiac boys, and with the 305 who followed there, are felt to have been in a measure *better than those since obtained* under necessarily *more directive and repressive methods* in the main institution. It was there learned that a first problem is to get convalescent cardiacs, even boys, to exercise enough and that they will well-nigh *automatically grade into the higher exercise activities* safely and, if anything, too hesitantly.

Social Service Departments of hospitals and other sources of these patients generously assisted in completing a follow-through record involving personal investigation of the after lives of the 600 for from six months to two years.

"*Good convalescence*" in the following classification signifies such gains in heart functioning and in general physical and mental condition as to justify return to regular or specially adapted occupation, or to school (home keeping being classed as full occupation for women). "*Fair*" covers the cases making moderately good gains, leaving too soon for various reasons, but partially cooperative, retarded by complications (medical and social), and who were recommended for some further restorative effort, to handicapped occupation and to skilled follow-up. "*Failures*" include relapses, deaths, negative end-results (as in the too old, nephritic, or asthmatic), misfittings, such as homesickness and refusal to remain or harmonize, and are nearly all ascribed to faulty choice of applicants (medical, social, or temperamental). The pure failures under cooperative and full trial have been very rare indeed.

TABLE I—A SUMMARY OF EARLY RESULTS—1915 TO 1917

	Boys (10 to 16 years)	Adults (57% Males)
Number	130	470
Good convalescence	70%	55%
Fair convalescence	26%	27%
Good and fair	96%	82%
Failures	4%	18%
Average stay (of those who remained over 20 days, thus giving full trial)	44 days	46 days
Average stay of all	32 days	27 days
Average weight gain of full stayers	5½ lbs.	5½ lbs.
Steadily at school or work (2 years)	85%	34%
Part-time at school or work	7%	21%
Deaths since discharge	3%	10%
"Outlook" considered good, for fair health and productiveness	90%	70%
Readmissions to the Foundation (preventive, etc.)	6%	10%

The remaining percentages include those not traced, resting, sick, leading dependent lives, etc.

TABLE II—COMPRISES CHILDREN AND ADULTS—100 CONSECUTIVE CASES—BOYS AND GIRLS AND ADULT MEN AND WOMEN—TREATED 1919-'20

	Children (10-16 years, both sexes)	Adults (65% Men)
No. patients	159	241
Good convalescence	60%	46%
Fair convalescence	38%	48%
Good and fair	98%	94%
Failures	2%	6%
Deaths (3 adults, 7 10% of all)		13%
Average days stay (all above included)	30 days	24 days
Average weight gain (includes losers)	3 lbs.	3½ lbs.
Readmissions	4%	6%

TABLE III—AGE-GROUP COMPARISONS—100 CASES.

AGES	10-16	16-35	35 up
No. patients	159	118	123
Good convalescence	60%	55%	30%
Fair convalescence	39%	44%	59%
Good and fair	99%	99%	89%
Failures (4% of all classes)	1%	1%	11%
Deaths			3
Average weight gain	3 lbs.	2½ lbs.	3½ lbs.
Average days stay	30 days	25 days	21 days

TABLE IV—COMPARES DIFFERENT VALVULAR LESIONS

	Mitral	Aortic	Mitral & Aortic
No. patients	337	19	45
Good convalescence	67%	35%	55%
Fair convalescence	32%	54%	38%
Good and fair	99%	89%	93%
Failures	1%	11%	7%
Deaths		1	1
Average stay	25 days	21 days	29 days
Average gain	3¾ lbs.	2¼ lbs.	3¾ lbs.
No. lost weight	19	2	2

TABLE V—SUMMARIZES A GROUP OF CASES ADMITTED AS "ENDOCARDITIS," "MYOCARDITIS," "POSSIBLE" OR "POTENTIAL" HEART DISEASE, "TACHYCARDIA, ARRHYTHMIA, NEURO-CIRCULATORY ASTHENIA, ETC., IN WHICH NO VALVULAR LESION WAS DETERMINED.

Number of patients	99
Good convalescence	69%
Fair convalescence	69%
Good and fair	96%
Failures	4%
Deaths	
Average stay	20 days

Not enough time has elapsed to give adequate value to an after-life-follow-record of these 400 patients.

A TYPICAL REPORT ON PLACEMENT AND OCCU-

PATION AFTER DISCHARGE.—During twelve months of 1919-1920 sixty-nine of the Foundation's discharged heart patients (men), representing both good and fair convalescence, sought work through one special Bureau for Employment of the Handicapped in New York City. Of these, sixty-four were newly and well placed, one was returned to his former job and another to his western home, one was too young to obtain working papers, while two were considered too ill for placement when they came to make application. At the end of the year fifty-nine held their positions, the majority being in improved health and contentment, ten had been back in hospitals with heart attacks for short periods, fourteen others had heart treatments as out-patients, and one elderly man had died suddenly while at clerical work. Fifty-five were still co-operative with their Cardiac Clinics. This group was considerably below the average of discharged patients in physical and economic fitness, some of them not having previously worked for months or years.

Notes.—Although the average stay appears as about four weeks, it should be emphasized that the standard successful treatment period is from four to eight weeks, the lower average of total being brought about by the large percentage of atypical and short stay patients; for example, the 30 per cent. who left too soon for various good and poor reasons, and the many and most valuable preventive recuperations requiring but briefer residence.

It is repeatedly and quite properly questioned whether four to eight weeks of such régime can produce any considerable and lasting benefits to this class of patients with seriously damaged hearts. The affirmative answer is given measurably by results observed in this broad experiment, and confirmed by the large body of physicians, skilled welfare workers and others who have noted the physical and economic product of it during the past five years, and who press with increasing numbers of applicants for the treatment. Its practicability depends, however, upon cooperative organization extending from hospital entrance through convalescence on to life work and follow-up, and this short exercise treatment is to be properly regarded as but one link in this chain of reconstructive effort. And the shorter term carries many advantages. Institutional residence of more than a few weeks implies changed life (institutionalizing), a severance of those very ties to domestic, economic and civic environment (education, employment, home) which the whole reparative effort is trying to hold essentially intact.

The method of treatment at the Foundation, as described above, has proven in the main satisfactory. In a few border-line cases more precise tests of heart efficiency and reserve power are needed to aid in more accurately prescribing the exercises and in judging of fitness for return to certain modes of life and work. And the various work, play, and walking exercises fail in some measure of regular and effective application, as in the winter season, during periods of bad weather, and upon a considerable number of lethargic or uncooperative individuals. More exercise, and a more particular directing of the patients' active hours and exercises, is now being developed.

A CONCEPT OF X-RAY PATHOLOGY.

VI. ARTHROPATHY.

BY A. J. PACINI, M.D.,

WASHINGTON, D. C.

CHIEF OF LABORATORY AND X-RAY SECTION, HOSPITAL DIVISION,
U. S. PUBLIC HEALTH SERVICE.

In a normal joint four entities concern the roentgenologist; cartilage, synovia, ligament, and fluid. A joint may be considered a closed cavity between bones bounded by two tissues, cartilage and capsule. There is no bone tissue in the joint. Cartilage is normally radioparent, although past middle life and in certain conditions it may become slightly infiltrated with opaque calcium deposits making cartilage sufficiently radiolucent to a point where it may become visualized on an x-ray plate.

Before discussing the x-ray pathology of joints it is necessary to remark that the technology involved in producing a joint should be two-fold. First, the exposure should be such as to permit of the visualization of the bone surfaces just outside the joint in order to determine their relative relation. Secondly, an entirely different set of exposures should be made with the view of showing the soft parts that surround and involve a joint. In this second series of exposures all bone detail is, of course, lost; and it is desirable that it should be lost in order to make certain that the voltage used in connection with the current to produce the picture has been of a penetration adequately low to make for ready visualization of the soft parts. It is with an exposure made in accordance with the advice just given that the changes in cartilage, particularly those involving early infiltration of calcium salts into the cartilaginous fibers, the early villous proliferation of the synovia, and incipient clouding of the joint fluid, are recognized.

Cartilage.—Cartilage is potentially bone and is composed of cells and of a basement substance. The fundamental matrix appears homogeneous; but this homogeneity is apparent and not real. When the nutrition of cartilage is destroyed or if a joint is put to rest or out of function, the real fibrous nature of the matrix becomes evident. Deep in the cartilage the fibers are arranged at right angles to the surface, and, more superficially the fibers are arranged parallel to the surface. The fibers of cartilage thus described have sometimes been mistaken for flakes of fibrin in diseased joints. It seems probable that the frequency and importance of fibrin deposition in diseased joints has been somewhat exaggerated. Occasionally, there is seen a substance precipitated on the surface of the synovia that resembles fibrin, though it does not stain with the usual aniline dyes that color fibrin. In hemorrhagic exudate, fibrin is the natural constituent.

Cartilage draws its nutrition from the marrow which it immediately overlies, and probably, also, from the synovia (or periosteum) with which it is in contact. It has no blood vessels of its own. The rôle it plays in disease is much debated; but it seems reasonable to assume that its function is purely passive in any disease drama.

The joint cartilage forms an absolute barrier against the extension of disease from the bone into the joint, or from the joint into the bone,

so long as the nutrition in the cartilage is retained. If the nutrition of the cartilage is destroyed then it may become perforated and disease extend from the bone into the joint or vice versa. Until perforation occurs the only other means of extension must be at the cartilage periphery where the inner layer of the periosteum is connected with the inner layer of the capsule or synovia. Infections may find ingress and egress through this channel; malignant new growths do not appear to invade through this avenue. In general, it seems infallibly certain in x-ray pathology that in the cast of a pathologic process extending from one bone through a joint into another bone, that process is never one of malignant new growth.

Capsule.—This should be regarded as a continuation of the periosteum, and, like it, consists of an inner or cellular layer and an outer or fibrous layer. The inner or cellular layer is known as the synovia; the outer or fibrous layer is the ligament. They are not sharply differentiated; but the effect of disease upon them is so entirely different as to make them differentiated for the purpose of x-ray study. The ligament undergoes a purely passive rôle, the synovia an active rôle in disease. From the form of a ligament the x-rayist is able to infer increased fluid or increased tension in a joint cavity. This is particularly true in the case of the knee joint. The patellar ligament is normally revealed, with low voltage technique, as a convex arc, the convexity pointing posteriorly in a lateral exposure of the joint; and a concave arc when the entire joint is distended with effusion of whatever sort.

Synovia.—The inner layer of the capsule, or synovial membrane, forming the lining of the joint cavity, is a cellular tissue smooth for much of its extent but thrown into folds or villi called Haversian fringes at the recesses of the joints. When the synovia is inflamed its constituent round cells proliferate, oftentimes to great extent, the synovia undergoing a general villous growth. General villous proliferation of this character is to be regarded as a response to irritation and it may proceed as the result of disease in the membrane itself or because of an irritation in the joint cavity.

Ligament.—The passive fibrous capsular layer known as the ligament holds the ends of the bones together, checks motion and may be disregarded excepting for its mechanical changes in disease. When calcium deposit occurs in a ligament it is most usual to find an infiltration beginning at the point where the ligament originates from the fibrous layer of periosteum.

CLASSIFICATION OF ARTHROPATHIES.

Disease of the joints may be divided into: (I) The congenital arthropathies. (II) The static and the toxic degenerative arthropathies. (III) Arthropathies of circulatory origin. (IV) The inflammatory arthropathies (the arthritides). (V) The neuropathic arthropathies.—(Barker.)

Congenital Arthropathy.—Congenital arthropathy includes the absence of the joint, congenital dislocation, congenital forms of club-foot and flat-foot. Of these congenital dislocation of the hip requires particular mention. In this condition the

head of the femur may lie above or behind the acetabulum, the tip of the trochanter lying abnormally high. It is accompanied usually by a marked grade of lumbar lordosis. The x-ray is useful in showing the exact location of the head

FIG. 10.—Diagrammatic representation of Shenton arch formed by the obturator foramen and the neck of the femur. This arch can be seen as a continuous curve in any position that the hip is rayed.

of the femur. Through the use of the x-ray a distinction can be made between Heine-Medin disease (paralysis of the gluteal muscle causing a paralytic limb resembling congenital dislocation) and true congenital dislocation. In this connection it is useful to direct attention to the very valuable diagnostic line described by Shenton and commonly known as the "Shenton Line." It is an arch formed by the top of the obturator foramen and the inner side of the femoral neck, both connected by the visualization of a curve that normally exists but owing to bony interposition is not normally revealed. This line is the same in all positions of the joint, abduction and adduction alike. In discussing this topic Shenton says:

There are many lesions of the hip joint which will disturb this line. Congenital dislocation is a good example.

It is often said that the distortion of the rays makes appearances which resemble displacements in the hip region. To some people distortion may be deceptive, but no amount of distortion will affect this line. Anyone seeing a skiagram of a hip for the first time, and taking into consideration the intactness or otherwise of this line, could say with certainty whether displacement were present or not.

Another point is this, that radiograms of the hip region are very often most unsatisfactory on account of the thickness and density of the part. Few radiograms, however bad, will fail to show the femoral neck and the obturator foramen. Hence in this respect the diagnosis will be as correct with a very poor skiagram as with one in which there is the utmost detail.

Figure 10 is a diagrammatic representation of the normal Shenton arch, Figure 11 the broken Shenton arch in a case of congenital dislocation. These drawings are from actual radiographs and point to the great value of the Shenton line as a diagnostic in hip joint disarrangement.

The Static and Toxic Degenerative Arthropathies.—It is obvious that an important joint such as the hip joint depends for its maximum efficiency to some extent on the efficiency of regional joints such as the knee and ankle; and that any derangement in the regional joint, as in the knee or ankle, will be reflected on the hip joint which will suffer in function proportionally to the degree

of abnormality existing in the distal articulation. An extremity, therefore, may be considered a static unit; and any disturbance in one part of this unit will secondly affect the other parts. The secondary affections thus produced are called static arthropathies. These have been discussed at great length by Preiser, who asserts that most of the arthritis deformans or hypertrophic osteoarthritis may be regarded as static in origin.

Goldthwait's villous arthritis, common in the knee joint, appears to have a static origin. Of toxic degenerative disturbances there are two changes common to joints that need mention above others; these are ganglion carpi and lipoma arborescens.

Ganglion carpi is a villous mass appearing as a nodule on the dorsum of the carpus and apparently composed of a gelatinous disintegrated product derived from the connective tissue of the capsule of the wrist joint. It is usually radioparent to x-rays. Other tumors that appear in this region, most frequently neurofibroma, are radiolucent and sometimes radiopaque. They can thus be differentiated; it is sometimes possible to strike the ganglion carpi with the flat side of a book and immediately cause their disappearance much to the surprise of the one being examined.

Lipoma arborescens occurs usually in females, in middle life, and either at the medial or lateral malleolus. It is common in connection with various forms of chronic irritation of a joint. In the knee joint the fatty villi occupy the upper recess of the synovial sac in which region it most often produces a marked radiopacity readily detected by the soft ray technique previously discussed.

The sacroiliac joint is a locus critically considered as contributory to vague symptoms in that region supposedly arising from a subluxation. In testing for sacroiliac relaxation the leg of the patient is fully extended at the knee; one hand is placed over the patella, the other is used to lift the heel. If a subluxation of the sacroiliac joint exists, or if an arthritis involves this union, a pain irradiates from the back of the thigh owing to the slight displacement of the ilium on the sacrum.

FIG. 11.—Shenton arch broken by reason of posterior dislocation of the femur.

causing pressure on the lumbosacral because of the attachment of the ham-string muscles to the ischium.

From a study of the anatomy of the sacroiliac synchondrosis it is difficult to conceive how a luxa-

tion of this fibrous union can take place to any appreciable extent; and, if it does occur, it is not easy to see how it would appear on an x-ray plate. Baetjer very appropriately remarked the inadvisability of subscribing to the opinion that a subluxed sacroiliac synchondrosis, at least in its milder forms, caused definitely recognizable x-ray changes.

Arthropathies Following the Exanthemata.—Smallpox: There is a class of arthropathies that originate secondarily to the invasion of exanthems. This is true particularly in cases of smallpox in which the arthritis may occur during the desquamative stage and may proceed to suppuration. In some cases it appears to result from an invasion of the joint fluid by infectious toxins. These seem to enter the joint by continuity from the cellular layer of the periosteum into the cellular layer of the capsule or synovia. The irritation induces at first an increase in the volume and tension of the fluid; later, the cells of the synovia are stimulated to proliferate, throwing the membrane into villous projections that appear as radiolucent whorls under soft tube technique.

In the marrow the changes most characteristic of variola are produced. There is a central necrosis involving the blood-forming cells, a marginal infiltration of mononuclear elements and an abeyed production of leucocytes showing many disintegrated polynuclear forms. The bone nutrition is impaired and may go on to necrosis. Chiari describes the lesion as osteomyelitis variolosa; though the resemblance to other forms of osteomyelitis is nowhere observable. The arthritis incident to smallpox is usually polyarticular.

Measles.—Arthritis may follow the fever, or may originate during the height of the pyrexia. The arthritic changes are characteristically lymphoid in origin, invading the joint through the synovial layer. The changes are not unlike those produced in smallpox; a villous proliferative synovitis. There is sometimes a fibrous proliferation induced in the outer capsular layer or ligament. When the periosteum closely invaginates the articulation, and there is little joint-space, the fibrous proliferation may, rarely, occasion a fibrous ankylosis. Arthritis ankylosis following measles affected the jaw bone in a case reported by Osler.

Scarlet Fever.—Two forms of scarlet fever arthritis are recognized. The first is a suppurative form in which pus is poured into the joint, distending it and accompanied by highly toxic symptoms, usually ending fatally. Secondly, there is an arthritis very similar to a gonorrheal arthritis. This variety occurs most often during the second or third week of the exanthem. It attacks many joints, that is, polyarticular, and seems to choose the joints of the hands in preference to others. It may be accompanied by hemorrhage into the joint. In the second form, or scarlet fever arthritis without suppuration, the fluid volume in the joint increases sometimes to marked extent; the synovia is acutely inflamed but rarely undergoes sufficiently intense villous proliferation to be recognized under the x-ray; and there may rarely be observed a tendency to greater radiopacity of the ligament owing to the casual occurrence, in cases, of fibrous proliferation.

Rubella.—In German measles, arthritis may complicate; but it does not produce serious changes. The changes that are produced are usually too slight to be observed under x-ray.

While the exanthemata seldom, if ever, cause lesions that occasion x-ray inquiry, their study is valuable in order to gain a conception of the early changes incident to acute arthritis in which there is an increase of fluid in the joint. In diagram (Figure 12) the curve of a patellar ligament is represented in its normal contour, and in dotted line the contour it assumes when the tension or fluid of the joint is increased. *C* represents the femoral condyles superimposed; *T* is the tibial head; *P*, the patella; *QEFM* is the Quadriceps extensor femoris muscle; *PL*, the patellar ligament behind which is the infrapatellar pad. When distended owing to pathology the line *PL* assumes the contour indicated by the dotted line *S*. A synovitis with fluid increased can thus be recognized. For this study, it is preferable that the knee be flexed about 20 degrees, a lateral exposure made, and a soft tube technique used in which the bone detail is absolutely unstrived for, only the soft parts being revealed. A test for the value of a

FIG. 12.—The patellar ligament shown normally convex in the absence of pathological volume of effusion. The assumed convexity under pathological conditions is indicated by the dotted line.

joint x-ray plate lies in the distinctness with which the soft parts are revealed. Strange as it may seem, the most excellent plates, invaluable for the study of the x-ray pathology of joints, are those that appear decidedly inferior from a photographic viewpoint. Yet, with soft tube technique, it has been possible to reveal the cartilaginous calcific infiltration invading semilunar cartilages when these bodies were the site of pathology following their mechanical displacement or traumatic injury.

In various bursal inflammations, such as housemaid's knee, while readily recognized by the surgeon, are also distinctly revealed by proper x-ray technology.

Arthropathies of Circulatory Origin.—In these conditions the most important clinical variety of circulatory origin arthropathies is the bleeder's joint. Blood may enter the joint cavity as a result of trauma; but true hemarthros occurs in patients of hemophilic diathesis. It is commonest in one or both of the knee joints and is manifested by an increasing development in the amount of joint effu-

sion. The blood is more radiolucent than ordinary serous effusion and the fibrin sometimes flakes and precipitates. The appearance on an x-ray plate is characteristic and is due to the markedly engorged blood fluid joint, radiolucency where radiopacity should exist, and radiopaque fibrinous flakes floating in the fluid. Hemarthros may go on to fibrous adhesions. These adhesions may calcify and ankylosis result.

Infectious Arthropathies.—Any classification of infectious arthritides is ventured with trepidation. In defense of a classification that will be submitted it is clearly defined at the outset that it serves only for the needs of the roentgenologist.

Classification of Infectious Arthritides.—(1) Acute: (a) Traumatic, (b) Infectious. (2) Chronic: (a) Atrophic, (b) Hypertrophic.

The acute arthritides include those of traumatic origin and those of infectious origin. The traumatic arthropathies are considered conjointly in cases of inflammation that arise as a result of sprains, contusions, abnormal bodies in the joint such as displaced fibro-cartilage, joint mice and hypertrophied fringes. The fundamental pathology characteristic of acute joint inflammation incident to any of the above causes is centered in the accumulation of fluid in the cavity. It is manifested on the x-ray plate by the bulging of the patellar ligament already discussed and diagrammatically represented above. The fluid that pours into the joint may be serous or hemorrhagic. If it is serous it is barely to be distinguished; but if it is hemorrhagic, flocculi of fibrin soon deposit and may be visualized on the plate. The synovia inflames and thickens; and with soft tube technique the thickening may be demonstrated. As the inflammation progresses, villous proliferation is stimulated in the synovia. This is especially true in those arthritides that are accompanied by abnormal joint bodies owing to additional irritation incident thereto. Usually the joint is "favored" and spared, mostly because of pain. This makes for partial rest and leads to a fibrillation of the articular cartilage, the parallel striæ in the superficies of the cartilage becoming at first radiolucent, and progressively radiopaque, depending on the amount of joint rest. When the superficial parallel fibers have attained radiopacity, the deep perpendicular fibers become radiolucent. When the deep perpendicular fibers become radiopaque the arthritis has practically reached a subacute or semichronic duration. In an acute arthritis free from suppuration there is no bone involvement. If the arthritis is the result of a fracture, a local bone necrosis may enter into the pathology of the joint; but otherwise the x-ray pathology of arthritis is confined internally to the joint-space. With the finest technique the changes recorded may sometimes be elicited; but the value, thus far, in x-raying acute arthritis is that of excluding fracture, the symptoms of which often simulate an acute arthropathy.

The question of the diagnosis of a torn semilunar cartilage from x-ray pathology is easily answered. If the cartilage has been impaired and by its pathology interferes with the mechanical perfection of the joint, owing to its disturbed nutrition and to the irritation mechanically incident, it

undergoes calcification in a degree commensurate with the age and extent of the pathology. In the early stages the calcification makes a radiopaque cartilage radiolucent; in later stages the radiolucent partially calcified cartilage becomes radiopaque through additional calcific infiltration; so that in both cases if the proper technology is used a mechanically non-functioning or pathologically affected semilunar cartilage casts shadows that characterize its dystrophy in terms of x-ray pathology. There are many conditions that are clinically diagnosed as impaired semilunar cartilages that fail to show x-ray pathology. Some of these cases are perhaps general semilunar dystrophies in which the changes have not proceeded to an extent to record x-ray evidence; but others are improperly clinically diagnosed instances. Recently, a number of cases of chronic villous arthritis erroneously diagnosed semilunar trouble have come to attention in certain localities.

Loose Bodies In Joints.—Knox gives the following description useful in considering the character of a loose body frequently found in joints:

1. Synovial fringes in which proliferation of cartilage cells has occurred, leading to the formation of a nodular mass, which is at first pedunculated, and is then cast off into the cavity of the joint by rupture of the pedicle. These bodies are usually composed mainly of hyaline cartilage, with bony material in the center of the larger ones. They may become ossified throughout. They vary in size from about $\frac{1}{4}$ inch diameter up to 1 inch; the larger ones are usually longer than they are broad. There may be only one loose body in the joint, or there may be several hundreds. It is not uncommon to find one body quite loose, and one or more still attached to the synovial membrane of the same joint. (Radiolucent.)

2. Osteophytic outgrowths from the edge of the articular cartilage may become detached, and so form a loose body in the joint. These bodies are irregular in shape, and usually consist of a layer of cartilage covering an osseous center. (Radiopaque.)

3. A portion of articular cartilage with a thin layer of bone may become separated from the femoral condyle, and form a loose body in the joint cavity. This occurs probably as a result of injury. (Radiolucent to Radiopaque.)

4. A blood-clot in the joint may become gradually smaller and firmer, and so form a loose body. This occurs as a result of injury. (Radiolucent.)

5. A portion of the synovial membrane may become thickened and indurated as a result of injury. This is nipped by the articular surfaces during the movements of the joint, and finally, as a result of the rupture of the pedicle, the body becomes loose. (Radiolucent.)

6. In tuberculous disease of a joint one or several loose bodies may be found. These are composed of tuberculous material in the thickened synovial membrane. (Rice bodies.) (Radiopaque.)

7. Around a foreign body, such as the end of a needle, fibrous tissue may be found. This and the preceding type of loose body are rare. (Radiopaque.)

8. Partial detachment of a semilunar cartilage gives rise to a body which hangs into the joint. As this is usually still attached to the bone, it cannot be said that it is a true loose body. It, however, gives rise to symptoms of a loose body in the joint. (Radiolucent to Radiopaque.)

9. An innocent tumor, such a lipoma, may form in the synovial membrane, become pedunculated, and so hang into the joint cavity. This is very rare. (Radiolucent.)

10. A metallic body, such as a nail, bullet, or needle, may in rare instances form a variety of loose body in the joint. These, however, are usually spoken of as "foreign" bodies. (Radiopaque.)

Gout.—In gout the incident arthritis is really a form of traumatic arthropathy arising from the urate deposits that grate on the bone surface.

Gout affects mostly the small joints, generally the metatarsophalangeal of the great toe. It is accompanied by chalky deposits in various parts of the body but particularly in the cartilage of the external ear. The x-ray pathology of gout is characteristic and rarely needs the corroborative evidence of identifying aural cartilage calcification; but in cases of uncertainty a lateral exposure of the head will reveal in the cartilage of the ear marked calcific infiltration. This, in connection with changes about the joints would make for an inference of gouty arthritis. Immediately beneath an articular cartilage near the epiphyseal line gouged-out bone areas are found. These are small, clear, spherical areas, vividly described by Hirsch as though they had been produced by the use of a conductor's punch.

The cartilage space may be diminished in gout so that the bone surfaces of a joint are more closely approximated. A joint evenly covered with cartilage presents a uniform curvature; but in gout when the cartilage is irregularly eroded the even curvature of the underlying bone may become distorted, the uric acid or urate deposit accumulating in and around the joint. The deposit is recognized by the fact that it is more radiopaque than soft tissue but less radiopaque than bone.

Acute Infectious Arthritis.—The chief infective agents are pyogenic organisms, gonococcus, the typhoid bacillus, and the pneumococcus. Poynton and Paine have described a *Diplobacillus rheumaticus* that was thought to stand in etiologic relation to rheumatism. The organism is not mentioned in the later editions of standard bacteriological treatises. Rosenow discusses an oxygen-sensitive streptococcus which is considered of etiologic relation to rheumatism. The disease may be confined to synovia or it may also involve the marrow. When the synovia is attacked it shows the usual x-ray signs of inflammation as previously described. An exudate pours into the joint and may be serous, fibrinous, or purulent.

Gonorrheal Arthritis.—The changes revealed by the x-ray in a gonorrheal joint may be classed into three stages of infection. In the first stage there is increased fluid and periarticular swelling, but there are no characteristic changes; in the second stage there is marked destruction in addition to the usual signs of infection including synovitis and fluid increase; in the third stage there is greatly marked bony production with bony ankylosis. The knee joint is the one most usually attacked, when the under surface of the patella and the anterior femoral aspect show signs of the invasion. The inflammation may heal completely or may go on to chronicity. Destruction usually involves the cartilage on the under surface of the patella, which sesamoid sinks in towards the condyles of the femur. Hypertrophic changes appear on the margins of the patella and on the adjacent areas of the femur. Another change somewhat characteristic of this form of arthritis is the occurrence of small localized areas of rarefaction in the bone at the junction of articular surfaces and cortex. The development of spurs tending to grow out along the plantar fascia from the os calcis is supposed by many to be the result of gonorrheal activity. They are also to be observed in cases of streptococcus in-

fection. It is doubtful if there is any real relation between these spurs and Neisserian infection.

Typhoid and Pneumococcal Arthritis.—Both these types of arthritis are difficult to differentiate from that produced by ordinary infectious organisms. In typhoid as in pneumococcal arthritis marked bone production is the rule. A characteristic of typhoid arthritis is the frequency with which dislocation of the hip accompanies the typhoid arthritis. In pneumonia the arthritis is a serious complication, recovery from which is slow and ankylosis is usual.

Pyogenic Arthritis.—This is usually due to the cocci. In the acute form it may be mono or poly-articular. There is first an effusion into the joint activity, then the synovial thickening and proliferation. These signs may disappear; or they may proceed for several weeks when a decalcification of the articular ends of the bones becomes manifest, accompanied by an erosion of the cartilage and a subsequent narrowing of the joint-space. Later in the infection, when repair set in, hypertrophic changes may make their appearance at the margin of the articular surface. Occasionally the joint cartilage may be entirely destroyed and an ankylosed union result.

Generally speaking the x-ray is of less positive value in the acute arthropathies than it is in the chronic arthropathies. It is seldom that an exact etiologic cause can be ascribed to a very acute arthritis; and the true nature of the pathology may become apparent only after the process is well established and goes on practically to chronicity. Of the chronic arthropathies two main types may be differentiated.

1. Those that are characterized by a proliferation of the synovia and marrow with attendant atrophy of bone and cartilage. This includes chronic gonorrheal and syphilitic arthritis, tuberculosis in the large number of heterogeneous conditions under various names depending upon the classification adopted by the person describing the arthritis.

2. Cases characterized by degeneration of the synovia and marrow and incident hypertrophy of bone and cartilage. Under this heading are grouped those cases heretofore described as osteoarthritis, hypertrophic arthritis and degenerative arthritis. It includes also such lesions as Heberden's nodes and allied conditions.

Joint Tuberculosis.—Joint tuberculosis may begin in the marrow or in the synovia. It appears to exert a marked affinity for epiphyseal and lymphoid tissues, and if unmixed with secondary infections is rarely attacks any other tissue but simply affects them by interfering with their nutrition. Joint tuberculosis has already been considered in another paragraph. Clinically it may be confused with Perthe's disease. Perthe's disease, which occurs in children, resembles tuberculosis clinically but gives a different x-ray pathology and a different prognosis. In the cases thus far reported the disease has affected only the hip joint. Many cases that have been supposed to be tuberculosis, followed by recovery, are now thought to have been Perthe's disease. In the joint in Perthe's disease there is a disturbance of the epiphysis involving the deposit of calcium and some thickening of the head, but

always a clean cut and clearly defined point. In tuberculosis, it will be recalled, there is a haziness of the part invaded. A joint which has been attacked by Perthe's disease may resume a normal appearance after five or six years. It occurs between the ages of six and twelve years and is confined to the epiphysis. Adults appear to be free from the affection.

Syphilitic Arthritis.—Joint syphilis is more frequent than is generally recognized. It may occur in the joints in two differentiated forms. The first form corresponds to the synovial form of joint tuberculosis, the second occurs under the affection known as Charcot's joint. In the synovial form there is synovial proliferation and increased fluid in the joint. In addition there is periarticular swelling and a periosteal reaction. Charcot's joint had best be considered under the neuropathic arthritides.

Atrophic Arthritis in General.—Atrophic arthritis is usually a middle age condition and is accompanied by atrophy in the soft tissues, limb deformity, absence of swelling and motion limitation due to fibrous changes. The x-ray pathology indicates atrophy of the soft tissues and bone absorption of cartilage, occasional destruction of cartilage, but no new bone formation. Atrophic arthritis may resemble the arthritis that accompanies an infectious type in its second stage from which it is often impossible to effect a differentiation.

Chronic Hypertrophic Arthritis.—This is a condition most generally asserted in people of middle and old age. It is most pronounced in those of fifty years and over. The x-ray pathology is characterized by very little atrophy, more condensation and exostosis. There is marked lippling; joint mice are characteristically present in some cases. When they are present the condition is distinctly hypertrophic. The head of the bone assumes a more or less mushroom shape.

General Conception of the Arthritides.—The entity arthritis of infectious type may involve three stages of x-ray pathology. First, a stage in which there is an acutely inflamed joint accompanied by an increase in the amount of fluid and by periarticular swelling. No bone destruction or atrophy is present in this stage. In the second stage the swelling has disappeared and atrophy begins, the disease has usually subsided and the fluid absorbed. The joint surfaces, owing to the destruction of cartilage, become more nearly approximated. In the third stage repair is inaugurated, atrophy disappears and there is a replacement of the destroyed bone and cartilage. A proliferation of new bone is observed sometimes in the formation of bony exostoses; and where the cartilages have been destroyed the entire joint may become ankylosed. The x-ray pathology of an arthritis of whatever origin could fall in one of these three stages. A valuable x-ray classification would be to describe an arthritic condition in terms of three varieties:

1. Subintensive arthritis manifested by swelling and synovial changes. This would include all of the arthritides discussed under the acute forms in the classification above given.
2. Atrophic arthritis manifested by changes in the bone density and by cartilage destruction.
3. Hypertrophic arthritis manifested by an in-

crease in the bone content on the joint appears by exostoses and other evidence of calcific proliferated changes.

Special Joint Conditions.—Chronic villous arthritis can be recognized by the x-ray in lateral views of the knee when in the posterior portion of the capsule there can be visualized a radiolucent mass, stringy, fan-shaped and radiating internally between the condyles of the femur and tibia. It may be of an infectious origin. It occasionally involves the knee, in which type it may appear as a form of static arthropathy. (Goldthwait.)

Heberden's Nodes.—Heberden's nodes are due to excrescences on the base of the terminal phalanges of the fingers. They may occur associated with hypertrophic arthropathies, or in gout, or may occur as an isolated phenomenon or associated with arthritis of the other joints.

Still's Disease.—Still's disease is a chronic arthritis of childhood, seldom recognized and without definite clinical or etiologic unity.

Neuropathic Arthritis.—Under this title the most important joint condition is that of Charcot. It occurs in tabes or syringomyelia and in other chronic diseases of the spinal cord or of the peripheral nerves. A tremendous swelling of the soft parts usually ushers in the affection. The articular surfaces of the joint are completely destroyed and the articulation entirely disorganizes. Large irregular masses of calcified material, radiopaque, become scattered throughout the joint. It is most common at the knee, hip, ankle, and spine. In ordinary infections the cartilage is first destroyed and then the bone. In Charcot the most distinctive sign aside from the destruction is the absence of atrophy and the presence of eburnation. The picture is diagnostic and quickly recognized.

PYURIA.

By ABR. L. WOLBARST, M.D.

NEW YORK.

CYSTOSCOPIST AND CHIEF OF UROLOGIC CLINIC, BETH ISRAEL HOSPITAL; CONSULTING UROLOGIST, CENTRAL ISLIP AND MANHATTAN STATE HOSPITALS; ATTENDING GENITO-URINARY SURGEON, WEST SIDE DISPENSARY AND HOSPITAL.

PYURIA (pus in the urine) is a symptom, not a disease. Briefly defined, it is a manifestation of an inflammatory process somewhere in the body in close proximity to the urinary stream. This process may be localized or disseminated, involving one portion of the urinary tract or several. Discovery of the pus usually is made by the physician quite accidentally in urinalysis made in the course of a general examination for some complaint, for pyuria need not be accompanied by other symptoms.

The etiology depends largely upon the location and character of the inflammatory process. There may be an infection by bacteria of some part of the tract otherwise normal, or this infection may be superimposed upon calculus, foreign body, tumor, stricture, etc. It is therefore of prime importance to localize the source of the pus before a diagnosis can be attempted. We must not confuse pus in the urine with cloudiness. The latter may be due to the presence of urates, phosphates, bacteria or chyle in large quantities. All of these can be determined quickly by simple analytic tests, which

need not be described here. The thing to remember is that these substances are frequently found in the urine and that they must not be mistaken for pus.

Having determined that we are dealing with pus, the problem of locating its source is by no means a simple one, because one or several portions of the urinary tract may be involved. In the male the pus may have its origin in the urinary tract (kidney, ureter, bladder), in the genital tract (prostate, seminal vesicles, posterior urethra), in the common urogenital tract (penile urethra), or in any combination of these.

In the Female: Pyuria in the female invariably is urinary in origin, except when the urine voided by the patient has become polluted with pus derived from the genital tract through the existence of a fistulous opening, through uncleanness, or through carelessness in obtaining the specimen. But if the vulva and the external urinary meatus have been cleansed carefully, any pus found in the voided urine obviously emanates from the urinary tract.

The diagnosis as to the origin of the pus is made by first eliminating the urethra as the point of origin, thereby bringing the investigation within the sphere of the urinary tract proper. The urethra in the female is eliminated from consideration by means of several irrigation tests, the simplest and most practical of which is the following: The urethra having been cleansed through a fine recurrent catheter and the washings collected in a clean glass vessel, a sterile catheter of fine caliber is inserted into the full bladder and some of the urine withdrawn. If this urine is clear and the collected washings contain pus, no further proof is required to show that the pus originated in the urethra. If the washings are clear and the catheter drawn urine is cloudy (with pus), it is evident that the pus does not originate in the urethra. The importance of this test, and others having the same end in view, is that urethral pus in the female often acts as a misleading element in the diagnosis of pyuria. One is apt to forget the fact that the female urethra is subject to infection and inflammation in the same manner and under the same conditions as its prototype in the male sex.

In the Male: Because of the more intimate relationship existing between the genital and urinary tracts in the male, the problem of locating the origin of the pus is much more complicated. We have to determine whether the pus is derived from the urinary tract proper, from the genital tract proper, or from the common urogenital tract.

As in the female, we first must eliminate the urethra as the pus focus, this being the most common source of pyuria in the male, due to the frequency of acute and chronic gonococcal infection. The existence of a more or less profuse discharge at the meatus at once suggests the probability of the urethral origin of the pus. It is essential, however, in the interest of a correct diagnosis, to determine in which portion of the urethral canal the pus originates. With this end in view, various "tests" have been devised, all of them being possessed of some distinct merit. For lack of space, they need not be described in detail at pres-

ent; the reader can find them described fully in previous publications.* They are designated as follows: Thompson two-class test, Smith irrigation test, Goldenberg-Jadassohn irrigation test, Kollmann five-glass test, Jadassohn expression urine test, Young seven-glass test, Wolbarst five-glass catheter test, Kromayer methylene blue test, and Lohstein ferrocyanide test.

With the aid of one or more of these tests, particularly the Smith and the author's tests the exact origin of the pus in the male urethra can be determined and suitable therapy instituted. The methods of employing these tests have been gone into in detail in the publications above referred to. If, however, these tests show that neither the urethra nor the adnexa is the source of the pyuria, it becomes quite evident that it must have had its origin somewhere in the urinary tract proper, that is, the bladder, ureters or kidneys.

The urethra having been eliminated, the problem is the same in both sexes, and similar methods of investigation are applicable. It is in the investigation of the urinary tract proper that the cystoscope and the ureteral catheter prove their estimable value. A diagnosis in pyuria of urinary origin, made without the cystoscope, would be equivalent in value to a diagnosis of optic atrophy made without the ophthalmoscope.

In the bladder, the principal causative factors in the production of pyuria are cystitis (acute and chronic), stone, tumor, foreign body, tuberculosis, obstruction to the urinary flow and retention. In each of these conditions the cystoscope is the diagnostic medium par excellence. With its aid the bladder condition readily can be seen and studied, and a diagnosis made with considerable accuracy. It goes without saying, of course, that the cystoscopist not only should see well, but should know what he sees and give his findings their proper interpretation; otherwise, the cystoscopic picture loses much of its proper value as a diagnostic aid. To the trained eye a gross error in the diagnosis of pyuria of vesical origin is practically impossible. One may err in calling a bladder tumor benign when it really is malignant, or vice versa, but he cannot fail to see the tumor. The same is true of other vesical lesions predisposing to pyuria.

When, however, the question of determining whether the pus originates in the bladder primarily or at some point higher up in the urinary tract is to be decided, several other measures are available. A "snap" opinion may be expressed, for example, as the result of irrigating the bladder through a soft catheter. If the washings come out clear after but one or two irrigations, the fact is strongly suggestive of a renal or ureteral pyuria being present; if, however, it requires much washing for the return flow to become clear, the probability is that we are dealing with a vesical pyuria.

Some observers attach importance to the behavior of the pus in a vessel into which the urine has been voided. They believe when the pus settles quickly to the bottom of the vessel, the pyuria is renal in origin; if it remains suspended and

**American Jour. of Urology*, December, 1908; *International Clinics*, vol. 1, 22d Series; *N. Y. Medical Journal*, May 13, 1916.

mixed with the urine for some time, the pus is vesical in character. To quote Keyes: "The (kidney) pus sinks to the bottom of the glass and lies flat and solid like a bed of sand, while the supernatant fluid remains hazy with bacteria." * * * * * "Bladder pus never settles in this way. However intense the cystitis, however deep the layer of pus at the bottom of the glass, it is always capped by a fluffy, rolling muco-cloud (like the thunder head on the horizon of a summer sunset) if the pus comes from any part of the urinary tract except the kidneys."

Microscopic examination of the centrifugated urine is said by some expert microscopists to give a definite and positive clue to the renal origin of pus, but this view is not generally accepted as absolutely proved beyond doubt. It is often impossible even for the most expert to differentiate satisfactorily between pelvic epithelium and some of the forms derived from the deeper strata of the lower portion of the urinary tract.

Another fact worth remembering in this connection is that kidney pus usually is found in acid urine, while pus found in alkaline urine generally is of vesical or prostatic origin. It is equally important to remember that too much reliance is not to be placed on this distinction, since there are many exceptions to this rule.

The method par excellence, and the one that should be employed in every possible case, is ureteral catheterization. A final, definite decision as to the origin of the pus cannot be made without this invaluable procedure. It need not be emphasized that every precaution must be taken thoroughly to empty the bladder of any contained pus before the catheters are introduced into the ureters; otherwise some of this pus may be carried into the ureters and a possible erroneous diagnosis (to say the least) may result.

The ureteral catheter is the court of last resort in the diagnosis of pyuria originating in the urinary tract, and when carried out under strictly aseptic conditions by skillful hands, the resulting findings are beyond question.

In any given case of pyuria which has been traced by exclusion to the upper urinary tract, if the urine obtained through ureteral catheterization is free from pus, microscopically as well as macroscopically, the source of the pus positively is not in the kidney. Several separate examinations may be necessary in certain doubtful cases before the kidney can be absolved absolutely, because it is barely possible that there may be a momentary cessation of purulent secretions in such a given case. Repeated examinations of the catheterized urine, invariably giving the same negative result, must be considered conclusive, and the origin of the pus must be sought elsewhere.

It may be observed, in closing, that this paper deals exclusively with the subject of pyuria considered as a symptom, and does not take into account other symptoms that might be of assistance in locating the source and determining the character of the pyuria. It is the intent of the writer to point out the fact, so often overlooked, that pus in the voided urine can be made to tell its own story and that a diagnosis, correct almost to the last de-

gree, can be made by a conscientious study of the urine and the passages with which it comes into contact. In making this diagnosis, however, the urinary tests above referred to, in association with the cystoscope and ureteral catheterization, are absolutely indispensable. Without them pyuria inevitably must remain an unsolved enigma.

792 LEXINGTON AVENUE.

THE CAUSE OF DEATH FROM NITROUS OXIDE-OXYGEN ANESTHESIA.

BY J. F. BALDWIN, M.D.,

COLUMBUS, OHIO.

SURGEON TO GRANT HOSPITAL; CONSULTING SURGEON TO CHILDREN'S HOSPITAL, ETC.

THAT nitrous oxide-oxygen anesthesia is not the safe anesthesia which its advocates originally claimed but, on the contrary, is one which has developed a large mortality, is a fact which is well known by all anesthetists who have kept in touch with its use. Comparatively few reports of deaths have gotten into the literature, but that the number is comparatively great is beyond dispute. The largest number of deaths reported by any one observer were those reported by myself in 1916 (*MEDICAL RECORD*, July 29, 1916). That report showed that in Columbus the nitrous oxide-oxygen death rate had been practically 1 per cent. in administrations for major operations. Since my paper was published another death has been unearthed which occurred during the period covered. Following that report the administration of the agent for major operations practically ceased in Columbus, but a few months ago for some reason it was used in another case, with prompt death on the table, death in that case taking place, as in the others, suddenly and without the slightest warning.

In the Anesthesia Supplement of the *American Journal of Surgery*, of July, 1917, Dr. Dennis E. Jackson, of St. Louis (Associate Professor of Pharmacology in Washington University Medical School), presents an exhaustive paper reporting experimental investigations into the pharmacology of nitrous oxide. He does not, however, go into any details as to its lethal effects, but simply says: "I have observed that *dogs* under nitrous-oxide-oxygen anesthesia may not well withstand extensive operations, particularly if the abdomen is opened and the viscera manipulated in any way." Publication of this article led to some correspondence with the author, in which he enlarges as follows upon the actual causes of death during the administration of nitrous oxide-oxygen:

It is extremely probable, however, that nitrous oxide does not directly poison the heart itself. Its action here is solely an indirect one, for the gas is apparently entirely indifferent to the heart. The action on the heart is indirect, first by limiting the supply of oxygen, and probably secondarily by hampering the excretion of the CO. These two factors, or at least the first, are apparently always present before the heart is in any way disturbed. A further action (indirect) which the gas has on the heart seems to be a result of medullary stimulation of the cardio-inhibitory center. There is some evidence that the N₂O stimulates the medulla at first (like ammonia). In a heart that was especially susceptible to inhibitory influences (vagi), this might set up irregularities which could pass over into partial or complete heart block, or possibly into ventricular fibrilla-

tion. The asphyxia which would certainly be present would cause some sympathetic stimulation (asphyxia of the cord), which would tend to cause the heart to become more irritable and therefore more likely to become irregular. If this factor predominated one might very well expect the possibility of sudden death from ventricular fibrillation after the manner which Levy has described for sudden death under chloroform. I had one or two animals in which I suspected at the time that this had actually occurred, as a slow sporadic gasping respiration continued for a while. But if the condition actually existed in the heart the later developments do not always bear it out, for I got one or two of these animals to recover by artificial respiration and massage of the heart. Recovery of the heart after ventricular fibrillation has begun is an exceedingly rare thing.

On the other hand, the marked slowness of the heart which occurs readily in dogs may be due to strong vagus inhibition. Asphyxia (of the medulla) causes a rise in blood pressure, and if the rise is considerable the intracranial pressure mechanically stimulates the vagus inhibitory center. This would slow the heart. But asphyxia of the heart itself is almost undoubtedly the contributing factor, for the heart may be slow when the pressure is low. And I believe that the statements of anesthetists that no asphyxia was present when death suddenly occurred should be taken with a good big grain of salt. For the essential features of asphyxia exist out in the tissue cells, and no one knows what effect either the presence of nitrous oxide or the absence of the normal percentage of nitrogen from the blood and lymph, or the inhibition of the normal elimination of CO₂ into the lymph, or the absorption of the oxygen by the cells from the blood (through the lymph) may have on the metabolism of the body in general (or of the heart or respiratory center in particular) when these are all present at once, as is the case in nitrous oxide anesthesia. Furthermore, I suspect that death may occur under nitrous oxide from depression of the respiratory center, due to the depressing (later) effects of the gas, coupled with the excess of CO₂ and lack of oxygen which are fairly sure to exist.

Thus it seems possible that death under nitrous oxide (at least in dogs) may occur from one or more of three causes, viz., central respiratory depression, excessive cardiac inhibition (as explained by Embley for chloroform), or ventricular fibrillation. It is possible that in all cases each of these conditions tends to be present, but one or the other predominates. And the character of the death and its attendant symptoms should vary according to its cause. It is probable that this variation explains the discrepancies in the literature regarding the nature and cause of death under gas.

While these statements by Dr. Jackson are exceedingly enlightening, it is to be hoped that he or some other equally competent experimenter will make a special study of the cause or causes of death to determine just what particular factor may be regarded as chiefly at fault, so that anesthetists, if possible, may guard against this source of danger, or may abandon the use of this anesthetic if its dangers cannot be overcome.

UNILATERAL AUDITORY HALLUCINOSIS.

By HAROLD S. HULBERT, M.D.

OAK PARK, ILL.

KRAEPELIN and others have referred to the fact that sometimes in dementia precox the hallucinations are unilateral. I have had an opportunity of observing a large number of cases of dementia precox on the first day that the psychoses caused sufficient disorder of conduct to suggest to their associates that the patients be submitted to a psychiatric examination. While psychiatrist at the United States Naval Training Station at Great Lakes, when it was the largest naval training station in the history of the world, cases of suspected

mental disorder would be brought to me, sometimes within one-half hour and always within a few hours of the first signs of mental disorder. Because of the tremendous pressure of military work in times of war, it was not possible to prepare careful charts and tables of unusual signs and symptoms. Therefore, I cannot submit statistics, but must rely upon my general impression, both confirmed and re-confirmed by newer cases.

It was almost the rule to find in these patients who had hallucinations for the first time that the so called "voices" were heard only in one ear. Later while I was psychiatrist on the U. S. S. *Leviathan*, an armed U. S. Naval Transport, which had a ship's company of over 2,000 men, several cases of dementia precox developed in the crew. Also among the 10,000 troops each trip being transported to France, quite a few cases of dementia precox developed aboard ship. These men were brought to the sick-bay for examination and treatment because the Commissioned Officers, Petty Officers, and non-Commissioned Officers noticed that their conduct was unusual. Here again I made the same observations made ashore, i. e. that almost always in the cases which I diagnosed as dementia precox, if there were auditory hallucinations, the patients commented on the fact that it was a novel experience to hear voices when no one was around, and, on questioning, I usually ascertained the fact that voices seemed to be localized in only one ear. Before and after the armistice it was my duty to bring home on the U. S. S. *Leviathan*, which was now partially a hospital ship, but largely a transport, about 300 A. E. F. neuropsychiatric cases a trip, altogether between 2,000 and 3,000 such cases returning on board ship on my wards. In the re-examination and review of the diagnoses for the purpose of treatment and special custody in the strange environment of a submarine-hunted ship in war time, I found many cases of dementia precox whose psychoses were of extremely short duration. In these I found that the auditory hallucinations began only on one side. In many cases the hallucinations became bilateral, but remained localized, good voices being heard in one ear, and bad voices in the other. In civil practice subsequent to the war, this condition was found in several patients, but had to be brought out by questioning them as they seldom spontaneously mentioned that voices were seemingly heard only in one ear.

I have come to the conclusion that the usual course of these misunderstood pseudo-exteriorizations of new or strange thoughts is somewhat as follows: At first the hallucinations are localized only in one ear; later, they may be localized in both ears, or the good voices are identified as coming from one side and the bad voices from the other. The patient may hear contradictory voices in the opposite ears, on one side saying, "Do this thing," and the other side saying, "Do not." The patient may imagine that he hears the voice of one individual speaking in one ear and the voice of another individual speaking in the opposite ear; he may hear male voices in one ear and female voices in the opposite ear, or blessings in one ear and curses in the other ear. Another form of localization is found in patients who are of foreign birth or foreign stock, and who consequently speak a

foreign language, claiming that in one ear they hear voices talking to them in English, in the other ear voices talking to them in their mother language. Later this localization fades as the case becomes chronic and not acute; still later it is frequent to have the patient state that "voices do not bother me any more"; later yet, that he hears voices only at rare intervals, and eventually that he does not hear them at all. Exceptions to this are found in cases which remain acute for long periods of time. The word acute is often given a double meaning in medicine. Sometimes acute means severe in contrast to mild; at other times acute means recent in contrast to chronic. I have in mind a case whose condition remains acute after a lapse of several years, because it is impossible for him to adjust himself comfortably, due to the persistence of factors which led to or which aggravated his mental trouble.

CASE.—The patient is a white male, age 30, who has been deformed since infancy. He has scoliosis. As a child his brothers made fun of his deformity. Disappointments have been his rewards in life. Even when they took him out on their pleasure trips, as to a party, they would laugh him out of the games, or might even leave him on the porch if they were going into the house of a neighbor.

His father is an alcoholic, although he came from an extremely religious stock. His mother has remarried and made a home for the patient, but the step-father is also alcoholic. The mother herself, is extremely unstable emotionally, and does not show very good judgment in handling the affairs of daily life. The patient had a fairly good education and worked at an instrument in a telegraph office. His contact with girls and women had been extremely limited. When he would make ordinary advances to girls whom he met, such as asking them to dinner or to the theater, he would be told to run along, as they did not care to go out with a hunchback. Three times in his life he had intercourse with women. Twice with common prostitutes for money, and once with a mistress of a fellow employee. He felt that he never could get acquainted with nice women. He reached the time in life when most men were establishing their own homes. He never could remember having been in a natural home because of his father's drunkenness and later divorce. He sat beside a rather attractive young woman who worked in the same telegraph office. For about two years he came in daily contact with this young lady. He spoke to her only once. He began to desire her tremendously. He realized that she was unobtainable. The thought was unbearable to him. He began to complain of failing vision, and as an explanation for that said his mother must be putting olive oil into his tea to affect his eyesight. He quit work, stayed around home, and one time tried to reconcile his divorced parents, even though his mother was legally married to his step-father. He was committed to the Hospital for the Insane. Here hallucinations developed. For the first time he heard Helen speak to him. He said that he heard her voice in his left ear. She stated that she loved him, that she would come out to see him, that she was an orphan, and when the patient was told to commune with her and ask what she thought of his physical condition, he put his hand to his left ear, shut his eyes, and in a few minutes looked up and said, "She says, 'You have the most beautiful brown eyes I have ever seen.'" The examiner's attention was immediately drawn to his eyes and truly they are handsome. The hallucinations continue but are not so constant as they were earlier in the psychoses. They continue localized on one side. It is impossible for this man by sublimation or otherwise to overcome his realization that his deformity will prevent the fulfillment of his desires, i.e. he will never be able to have a family or home of his own.

Unilateral localization of auditory hallucinations has not been observed by me in other types of

mental diseases which have hallucinations, such as acute alcoholic hallucinosis, deliria with fever, etc., unless there is organic disease of one ear or greater organic disease of one ear than the other.

CONCLUSIONS

(1) Unilateral localization of auditory hallucinations is frequently found in early or acute cases of dementia precox and is not found in other conditions unless there is some organic disease of the nervous system or of the auditory apparatus.

(2) Hallucinations are usually first localized on one side, then become bilateral, with different characteristics on the two sides, subsequently become bilateral with similar characteristics on both sides, and finally, either cease to bother the patient or cease to exist when, through apathy, he no longer feels the need of rationalization of strange or new thoughts by exteriorization.

(3) The continuance of unilateral auditory hallucinosis in the case of dementia precox where there is no organic disorder of the apparatus of hearing suggests that the case remains acute and the patient continues in the acute conflict stage without comfortable adjustment.

A CASE OF INTESTINAL INTOXICATION (HERTER'S INTESTINAL INFANTILISM).*

By SAMUEL Z. ORGEL, M.D.,

NEW YORK.

ASSISTANT PEDIATRIST, LEBANON HOSPITAL AND MT. SINAI HOSPITAL, O.P.D.; ADJUNCT DERMATOLOGIST, ISRAEL ORPHAN ASYLUM; ASSISTANT DERMATOLOGIST, MT. SINAI HOSPITAL, O.P.D.

A FEMALE child, 1 year old, was brought for advice because of its smallness of size and constipation. The family history was negative. It was a premature infant, born at 7 months. Weight at birth 3½ lbs. It was breast fed for four months, when nursing was discontinued because the mother again became pregnant. Child refused to take the bottle and it was fed from a cup.

Present Illness: Mother dates the entire trouble back to the time the child was placed on modified milk when four months old. Since then the child has gained comparatively little in weight and height. At the end of the eighth month it weighed 8 lbs. and was but slightly if at all shorter than at present. From the eighth month up to date it has gained 4 lbs. 5 ozs.

Child usually has two to three bowel movements a day; these are slate colored, voluminous and pasty, the amount being out of all proportion to the food intake of the child. Every third to fourth day the child becomes constipated and must be given an enema or laxative before its bowels will move. These attacks of constipation are associated with abdominal distention and the passage of large amounts of gas per rectum. The stool has an extremely bad odor. Urine is passed frequently. Appetite is good—in fact, excessive.

Physical Examination: Child, small, 25¼ inches tall. Weight, 12 lbs. 5 ozs. (normal height and weight being 28¼ inches and 20½ lbs. respectively). Well nourished, normal intelligence, and active. Head circumference, 16.5 inches (normal, 17.6). Anterior fontanel closed. Eyes: Slight slant. Dentition: No teeth erupted. Chest circumference, 17 inches (normal, 17.4). No external signs of rickets. Examination of the heart and lungs gives negative results. Abdomen shows slight distention, otherwise negative. Extremities are well developed in proportion to the size of the child; cold to the touch. Child is able to stand, but as yet does not walk. Wassermann negative in both mother and child.

Differential Diagnosis.—There was no doubt

*Read before the Society of Alumni of Lebanon Hospital, May, 1920.

†French's *Differential Diagnosis*, 3rd Edition, 1917.

that we had to do here with a case of Dwarfism. For convenience of dealing with this subject and for the purpose of diagnosis, dwarfism may be divided into two classes: namely, dwarfism the result of deformity, and dwarfism without deformity. Generally speaking, well-proportioned dwarfs owe their defective stature to a generalized delay or arrest of development, and are therefore in a state of infantilism, whereas deformed dwarfs are stunted in growth only, though the reduction in height may be due rather to the warping or collapse of the body framework than to actual curtailment of height.

1. Dwarfism, the result of deformity, will be considered briefly. This kind of dwarfism is due mainly or solely to shortness of the legs. In most cases the primary fault lies in the skeleton, but occasionally the dwarfism has its source in deficiency of the brain, and still more rarely is brought about by a local defect of development implicating the lower extremity.

A. Skeletal dwarfism is occasioned by: (1) Rickets; (2) achondroplasia; (3) osteogenesis imperfecta; (4) anosteoplasia, and (5) osteomalacia. All of these with the exception of rickets may be readily discarded without consideration.

Rickets may be excluded because of the absence of the following diagnostic points. (1) Sweating of the head; (2) extreme restlessness at night; (3) beading of the ribs; (4) craniotabes; (5) disproportion in the size of the head to the rest of the body; (6) the fact that that outside of the chief complaints of smallness in size and constipation, the child has been uncommonly healthy; (7) in this case we have an early closure of the anterior fontanel; (8) the marked strength and lack of easy fatigability; (9) there is an absence of all the external signs of rickets; (10) the impulse of growth is the last to disappear; a child may be greatly emaciated and underweight, but its growth in height is little interfered with if at all; (11) the child is able to walk. We failed to have x-ray pictures taken of the long bones in this case, so we cannot say definitely that some signs of rickets are not present; for occasionally one finds signs of rickets in the x-ray pictures of the long bones which are not detectable externally. From the above facts we think that rickets can safely be excluded.

B. Cerebral dwarfism: Under this head we have but to consider the microcephaly. The microcephalic dwarf is characterized not only by the relative smallness of his head (circumference never exceeding 17 inches) but also by his sloping forehead, projecting nose, and receding chin, giving him a ferret or rat-like physiognomy. He is usually quick of movement, and restless, and is either imbecile or idiotic, according to the degree of his microcephaly. Outside of the smallness of the head and the closure of the anterior fontanel there is no feature in common between the case in question and microcephaly.

II. Dwarfism the result of defective general development, infantilism.

Forms of Infantilism: Infantilism may be widespread among whole races or nations (racial in-

fantilism), or may select certain individuals or families, and occur epidemically or sporadically as morbid infantilism among people of ordinary development. Morbid infantilism is of two sorts, namely, symptomatic, the result of causes, and essential or cryptogenetic.

Symptomatic infantilism, the form that we think this case belongs to, is seldom or never of extreme degree, has no uniform type of physiognomy, and, being an acquired condition, is never transmitted. It is best classified according to the nature of the causes by which it is produced.

First we have those forms due to intoxication with the poisons of wine, tobacco, lead, syphilis, rheumatism, scarlet or other fevers. All of these we may readily exclude, for the history obtained shows nothing in their favor.

Second, thymic infantilism, may be excluded because of the absence of its most characteristic symptoms of fatness with anemia and liability to syncopal attacks which often end in death.

Third, deficiency of hormones which ordinarily stimulate development. There are two forms: (1) thyroid, and (2) pituitary. The thyroid form may be excluded, for its signs are unmistakable. The low temperature, the facial expression, the torpor, and the fatty tumors are enough to differentiate cretinism from the case in question. In the pituitary type there is fatness with conspicuous genital backwardness as well as general defect of development. Polyuria or glycosuria is often present; drowsiness, nutritional changes in the skin and its appendages, sickness, headache, and other symptoms of a cerebral tumor are present. All of which are here missing.

Mongolism presents characteristic symptoms not present in the case in point. We have not the oblique-set eyes of the Chinaman, the lax ligaments, the double-jointed thumbs, the marked backwardness in mental and physical development.

Cardiac and anangioplastic infantilism may be excluded because of the absence of any cardiac or arterial system defect.

Renal infantilism is excluded because of the absence of polyuria, albuminuria, or other symptoms of Bright's disease.

There are but two forms of infantilism left for discussion. These are: pancreatic infantilism and Still's or Herter's intestinal infantilism. The clinical picture in both bear a marked resemblance to one another, and one is oft hard put to differentiate between them. The stools two to three a day are large, voluminous, generally pale or slate colored; periods of constipation occur frequently, the large amount passed is out of proportion to the intake of food. The odor is extremely foul. There is an arrested development, the child stops growing and gaining in weight. The mental development is fair. Abdominal distention with moderate anemia and fatigue. Appetite and thirst are excessive. Hands and feet are usually cold.

Added to the above, there is a definite laboratory picture that goes with that type of infantilism known as Herter's intestinal infantilism. The urinary output is increased and shows an increase in ethereal sulphates, a pronounced indi-

canuria, excessive phenol and aromatic oxyacids. The feces should show gram positive organism, especially the *Bacillus bifidus* of Tissier, *acidophilus*, and *infantis*, as also an excess of fat, fatty acids, and soaps. The calcium and magnesium output is greatly increased. These necessary laboratory data, in order to make a definite diagnosis, we were unable to obtain because of the mother's refusal to send the child into the hospital for observation.

Treatment.—It is believed, as was expressed by Holt, Courtney, and Fales,* in an article in 1917, that greatly retarded growth, amounting to a condition of infantilism results occasionally from prolonged derangements of the digestive functions as well as a consequence of organic changes in these organs. These changes have generally been found to be connected with metabolic disturbances of the calcium, magnesium and phosphorus balance.

Knowing the demonstrated effect of cod-liver oil in increasing the retention of these inorganic salts, particularly in rickets, it was determined to try its effect upon the patient in question, a diagnosis of intestinal infantilism having been tentatively made.

Being unable to obtain the mother's permission for hospital observation, we decided to treat it as best possible in the dispensary.

Our treatment of this case can be briefly stated. The child was allowed to continue on a general diet of milk, cereals, farinaceous foods, with the addition of an egg, zwiebach, potato, cracker, and broth. The juices of stewed fruits also being allowed.

Therapeutically, the child was placed upon emulsion of cod-liver oil and phosphorus, thyroid extract also being given. The thyroid was given on the basis that there might be some thyroid deficiency.

Under this treatment the child immediately began to gain in weight, the gain being at the rate of about five ounces per week. The growth in height was less noticeable. The stool began to assume a normal color, the quantity to diminish, the putrefactive odor to disappear. The regular periods of constipation present heretofore, became a thing of the past, the child having three bowel movements daily. The appetite was unimpaired and if at all changed was increased.

By the end of the fifth week's treatment, the first lower incisor erupted, three weeks later the second lower incisor followed, and a week thereafter the first upper incisor erupted.

At the end of one month's treatment the thyroid extract was discontinued and the child was allowed to continue upon the emulsion of cod-liver oil and phosphorus. On stoppage of the thyroid the child showed a marked increase in the number of ounces gained per week. Whereas it had heretofore ranged from three to six ounces per week, it now jumped to from six to nine ounces per week, showing that the thyroid had no doubt markedly increased the metabolic processes of the child.

The data up to the present time show that

*Holt, L. E., Courtney, A. M., and Fales, H. L.: *Am. J. of Dis. of Children*, vol. 14:222, September, 1917.

during the period of 7½ months that the child has been treated, she has gained 7 lbs. 12 ozs. in weight, 4½ in. in height, the circumference of the head has increased 1¼ inches, the chest circumference 2 in., six teeth have erupted, the stools are of normal color, consistency, and odor and constipation entirely disappeared.

We have long known the ability of cod-liver oil and phosphorus to increase the retention of calcium and phosphorus by the organism; but as to how this is brought about has not yet been clearly shown. It no doubt must create conditions which allow the calcium intake to more easily become incorporated into the organism.

The administration of cod-liver oil we hoped would influence the salt retention in this case; for although laboratory data were unavailable upon this point, we nevertheless had very little doubt that the child's condition of infantilism was due to a lack of ability upon the part of the organism to retain the calcium and phosphorus brought to the child in its food. That our contention was justified can best be judged from the following table of the patient's progress throughout the time it was under treatment.

Progress of child from beginning to end of period of observation.

Weeks treated.	Weight.	Height.	Head Circum.	Chest Circum.	Teeth Erupted.
Admission	12-5	251 2"	161 2"	17"	None.

Dr. S. A. Blauner, whom I want to thank at this point for his great help and timely suggestions and for assigning me to this case, thinks that children of this type if allowed to go untreated, eventually develop into that type of intestinal infantilism so ably described by Herter in 1903 and which today bears his name.

9 WEST 117TH STREET.

A CASE OF ACUTE ARTICULAR RHEUMATISM COMPLICATING ACUTE OTITIS MEDIA.

By JOSEPH POPPER, M.D.,

NEW YORK.

ATTENDING PHYSICIAN, INFANT WELFARE DEPARTMENT, LEBANON HOSPITAL; ATTENDING PHYSICIAN, ISRAEL ORPHAN ASYLUM.

The occurrence of metastatic infection of the joints simulating rheumatism and following acute purulent otitis media is not uncommon. The latter condition is due to a real bacteremia following severe cases of middle-ear disease usually complicated by mastoiditis or lateral sinus thrombosis. Cases of this kind are frequently reported in the literature and they are described in the text-books. The oc-

currence of what appears to be clinically acute articular rheumatism following infection of the middle ear has been described only once by Oppenheimer,* quoting two cases reported by Wolf. Wolf himself, however, refers to his cases as being acute articular rheumatism complicated by otitis media, a statement with which Oppenheimer disagrees, believing the two diseases to have occurred in the reverse order.

The case I have to report is definitely one of acute articular rheumatism following acute purulent otitis media. It is therefore of interest both on account of its rarity and because it may be so easily confused with the bacteremic condition mentioned above.

History.—J. P., male, nine years old, was admitted to Lebanon Hospital, April 21, 1920, complaining of discharge from the left ear and pain in the right ankle. *Past History*: Had all the diseases of childhood with good recovery. Tonsils and adenoids removed two years ago. *Family History*: Irrelevant. *Present History*: Ten days before admission he was put to bed with a temperature of 102° F., complaining of headache, running nose, and slight, dry cough. Two days later he complained of pain in his left ear. That night there was a spontaneous discharge of pus from that ear. His fever, however, persisted, ranging between 101 and 104 until the day of admission. The discharge from his ear, meanwhile, became scanty, and on the eighth day of his illness an otologist was summoned, who enlarged the opening in the ear-drum, attributing his fever to insufficient drainage. Following this there was no noticeable increase in the discharge. On the ninth day the patient complained of pain in his back, which was followed the next day by pain and disability in the right ankle. *Physical Examination*: April 21, 1920. *General Appearance*: Fairly well nourished, but is pale and looks sick. Head: No tenderness anywhere. Eyes, including fundi, normal. Nasal mucous membrane congested. Right ear normal. Left ear: slight amount of mucus-pus present. Drum red, but not bulging. Small opening present in the lower posterior quadrant. Mastoid normal. Tongue coated. Teeth poor and many carious. Tonsils absent. Pharynx congested. Neck, heart, lungs, and abdomen: negative. Extremities: Right ankle warmer than the left and tender. No redness or swelling present. Spine normal. Reflexes normal. Blood examination: Hgb., 68 per cent.; W. B. C., 18,000. Poly., 78 per cent.; lymph., 22 per cent. Widal: negative. Blood Cultures: April 21 and 24, both negative. Urine normal.

Subsequent History: For seven days following admission he had pain, tenderness, and disability in almost all the large joints and in some of the small joints of the hands. He had swelling only in the left wrist. His left ear was normal on the fourteenth day of his illness. On the seventeenth day examination of the heart revealed a faint systolic murmur at the apex transmitted somewhat to the left and accompanied by a markedly accentuated second pulmonic sound. His fever continued to fluctuate between 101 in the morning and 104 in the afternoon until the sixteenth day, when it began to decline, reaching normal on the nineteenth day. With the decline in temperature the symptoms cleared up and his general appearance improved markedly.

Comment: The treatment of this case has an important bearing both on the diagnosis and the course of the disease. When first seen on admission the boy gave one the impression of being extremely sick, so much so that I felt almost certain that he was suffering from some form of sepsis. He was treated expectantly, therefore, until the report of the blood culture was available. Then, in the absence of chills and with a negative blood culture and no relief of symptoms, I came to the conclusion that it was a case of what, clinically, had

all the appearances of acute articular rheumatism as it occurs in childhood. He was then given salicylates, and in less than 24 hours there was a decided relief of all symptoms, with a marked improvement of his general condition.

This case also has a bearing on the moot question of the etiology of acute articular rheumatism. In spite of the many reports of bacteriological findings in this disease we are still in doubt as to any definite etiological microorganism. May it not be, therefore, that acute articular rheumatism is not a definite pathological entity, being rather a symptom-complex secondary to some focus of infection? Thus may be explained the well known connection between infected tonsils and acute articular rheumatism. Other obscure cases may be secondary to infections of the nasopharynx and ear, as in my case, or to infected nasal sinuses and teeth. Only further bacteriological and pathological investigation offers any hope of solving this problem.

628 EAST 163RD STREET.

Medicolegal Notes.

Misbranding Drugs Alleged to Have No Curative Value.—In a prosecution for shipping in interstate commerce misbranded drugs under the Federal Food and Drug Act of June 30, 1906, the Circuit Court of Appeals, Ninth Circuit, approved instructions which stated: "It is not proper in such a case as this to try rival well-established schools of medicine, and if you find that the defendant has only used in its several preparations homeopathic remedies for the alleviation of ailments, then your verdict should be not guilty, and you will not be called upon to consider any other question in the case. If you find, however, as a fact, that some or all of the preparations put upon the market by the defendant do not, in fact, contain remedial agents used in any school of medicine for the relief of the ailments for which it is put upon the market, then you will be called upon to consider the second question in the case, and that is: Did the defendant honestly believe that such remedy would have a curative effect upon the ailments for which it is offered to the public? The law requires that the Government must prove beyond a reasonable doubt, not only that the statements upon the labels are false, but also that the statements are fraudulent." It was objected for the defendant that the court allowed a medical witness for the prosecution to testify that the preparations which had been analyzed by a chemist and shown to the witness were absolutely worthless and had no food, curative, or medical value. It was held that the testimony was clearly admissible. In the case of *Seven Cases of Eckman's Alternative v. U. S.*, 239 U. S. 510, 36 S. C. 190, the United States Supreme Court held that the law does not reach one who puts inert matter or a worthless composition in the channels of trade, labeled as a cure for disease when he knows it is not.—*Kar-Ku Chemical Co. v. United States*, 264 Fed. 921.

Provision as to Sound Health on Date of Policy Does Not Refer to Chronic Disease.—The New York Appellate Division holds that a provision in a life policy that no obligation is assumed by the company unless the insured is in sound health at the date of the policy, and also an incontestability clause, where the company has had a medical examination merely means that he has not become ill between the time of making his application and the time of the issuance of the policy. It has no application to such chronic diseases as the insured may have had at the time of his application and medical examination. Any other interpretation would make the incontestability clause meaningless. This rule has been applied even to contracts that did not contain an incontestability clause. And this condition (sound health at the time of issuance of policy) may be waived by the delivery of the policy and the acceptance of the premium by the company's agent with the knowledge of assured's illness.—*Chenery v. Metropolitan Life Ins. Co.*, 182 N. Y. Supp. 555.

PEDIGREE OF EPIDEMIC ENCEPHALITIS.

As our knowledge of this affection slowly accumulates, including the inquest into the remote past, our conception of the pedigree becomes variously modified. At present, according to Lhermitte writing in the *Gazette des Hôpitaux* for Jan. 8, 1921, xciv, 3, the case of Albrecht von Hildesheim, 1695, since it was sporadic, should hardly be counted and the epidemic which was first recorded was that of Tübingen in 1712. The author then waives all alleged epidemic incidence until the time of Gayet in 1875 when this author described the pathogeny of the syndrome and showed that it must originate in inflammatory lesions grouped about the third ventricle and the aqueduct of Sylvius. Lhermitte now insists that most of the cases described by Wernicke in 1881 under the name of polienccephalitis superior hemorrhagica were examples of lethargic encephalitis. In 1887 Gerlier's disease was described and in the author's opinion must have been a variation of the same malady. Next in chronological order comes the malady, "nona," 1889-90, which showed such an extraordinary polymorphism that the profession was divided in opinion as to its nature, some even holding that it was a massed psychogenic affection. The author cites seven medical men who described nona and showed clearly that it was not a legendary affection, but it remained obscure until studied in the light of our recent knowledge, when it is recognizable as epidemic encephalitis.

Passing by certain Italian cases in the interim, probably because of their sporadic incidence, the author comes to the outbreak of 1916. But while this appeared in the same general area as older episodes the outbreak of the malady in regions outside of Central Europe and especially in remote Australia gave it a new status. There it was a frankly mysterious affection and one *sui generis* from the start. But its first appearance in England passed for botulism. Reports of the disease in such scattered parts of the world lent some plausibility to the spoiled food theory—an accident coming in the wake of the war. One cannot but admit that true botulism appeared in the same manner in widely scattered foci. Already there were marked local distinctions in the pathology. Thus the Austrian cases appeared to show menin-

geal involvement, which was notably absent in the French cases. The broad distinction between the lethargic and myoclonic forms became apparent and in Germany the latter may have predominated from the start with unusual clinical expressions—for example in Munich there was a pseudotabes. Italy, which had been visited by "nona," showed notable immunity in the present outbreaks, and when the epidemic appeared in 1919 the early cases were lethargic followed by the opposed type. When the disease reappeared in Austria it had assumed the myoclonic type. This sequence was certainly the rule but the author quite ignores the claim of Cruchet of Bordeaux that he recognized the myoclonic form at a period long antedating the appearance in France of the lethargic cases. In summing up, the author states that between the epidemic episodes sporadic cases have always been in evidence and cites a long list of authors who have described these cases, including such authorities as Thomsen and Oppenheimer.

APICAL RESPIRATORY INSUFFICIENCY AND THE DIAGNOSIS OF PULMONARY TUBERCULOSIS IN ADULTS.

As Sergent of Paris has recently remarked, there exists quite a large category of pseudo-phthisical subjects. He calls these by the apt term of cases of respiratory insufficiency. The diagnosis is especially necessary when respiratory insufficiency—instead of being complete—is exclusively confined to the apices. In these circumstances, the localization of the physical signs becoming added to some somatic characters and a few general symptoms, should the examination be insufficiently methodical, there may result a mistaken diagnosis. Cases of this kind are fairly frequent in practice and it is therefore essential to insist upon the symptomatic characters which specify this syndrome.

The syndrome is invariably bilateral and purely functional, which differentiates it from respiratory insufficiencies, the result of lesions and which are usually confined to one lung. The condition is particularly met with in adults, a fact which distinguishes it from total respiratory insufficiency encountered in children and which, for that matter, sometimes complicates it. The physical syndrome is the consequence of a decreased ventilation of the apices and makes itself manifest essentially by a decrease of sonority, vocal vibrations, vesicular murmur, amplitude of the respiratory movements, the absence of adventitious sounds, rough breathing, and souffle. Besides these signs, the various means of exploration concur in showing that the apices, although in a state of functional respiratory insufficiency, preserve the possibility of becoming momentarily sufficient, and this is precisely because no lesion exists that can hinder their ventilation and expansion.

The measures of functional capacity—spirometry, plessimetry—estimate the degree of the insufficiency. To this functional disturbance more or less accentuated general symptoms become added which are just the ones that lead *a priori* to a suspicion that

the condition may be tuberculosis, because of the insufficiency of weight and musculature, general hypotony, anemia and anhematosis, all of which attain a much more accentuated degree when total respiratory insufficiency complicates the insufficiency at first confined to the apices. The majority of these patients are young, but the syndrome may sometimes be met with in subjects over forty years of age. Almost all have had adenoids in the past and have been operated on some time previously, or else the nasal fossæ are impermeable so that they have lost the habit of breathing normally and no longer ventilate the lungs properly. Now, if this insufficient ventilation is at first confined to the apices it is because the apex is the region of the lung which in normal condition is the least ventilated.

The primary cause of this diminished ventilation of the apices, according to Sergent, should be looked for in insufficiency of movement of the diaphragm. In cases of injury of the base of the thorax—especially those of warfare—one can very distinctly see with the radioscopic screen that the apex—considering only intact apices—has a lesser transparency and expansion although preserving the possibility of offering the characters of a well ventilated apex when the patient is made to cough. On the other hand, in patients with nasal obstruction the diaphragm moves poorly. Therefore the mechanism of the syndrome of respiratory insufficiency of the apices, which is above all met with in subjects offering inadequate nasal respiration, is clearly explained, and it can readily be conceived why, if the diaphragmatic disturbance becomes extreme, total pulmonary insufficiency becomes installed, overshadowing the apical insufficiency which becomes only a localization.

The diagnosis of this syndrome is fairly easy when it is well known. Its bilaterality prevents confusion with insufficiencies due to apical lesions and bilateral apical sclerosis is practically the only morbid process for which it might be mistaken. But the physical signs and radiographic findings are very different in the latter process.

The absence of adventitious sounds and the perfect regularity of the respiratory sounds in both apices will prevent any diagnostic mistake. The prognosis depends upon the treatment employed. If this condition is allowed to continue it will inevitably react upon the general health because the somatic characters of the process are rather the effect than the cause of the functional disturbance. The treatment consists of respiratory reeducation and gymnastics methodically and progressively carried out.

ISOHEMAGGLUTINATION.

THE practice of "matching" the bloods of donor and recipient made the transfusion of blood a safe procedure. The demonstration of the fact that isohemolysis does not occur in the absence of isohemagglutination greatly simplified the methods adopted for testing bloods for incompatibility. Then came the investigations of Landsteiner, Jansky, and Moss which showed that all individuals could be divided into

four groups depending upon the way their bloods reacted. Transfusion performed between members of the same group was shown to be free from the danger of undesirable sequelæ due to the agglutination of the donor's corpuscles. This work made it possible to determine the group of a large number of individuals who might be called upon to act as donors and further simplified the procedure which was necessary when a transfusion became essential. Since this operation is generally an emergency measure the greatest possible simplification is desirable. But unfortunately Jansky and Moss adopted nomenclatures that were somewhat different in that the group I of one classification was the group IV of the other and vice versa. This difference introduced an element of confusion into the subject that was apparent during the war to some extent, for persons tested were informed of the group to which they belonged without being told of the classification. The danger naturally consists in a failure to retest donors in the hurry preceding a transfusion and introducing an incompatible blood into the veins of the patient.

The reason for this confusion is found in the fact that Jansky's paper appeared in a journal which is unfamiliar in this country, and although it appeared three years before the one by Moss, it was but little known. Moss's work gained immediate attention and his classification was used very generally in America and to some extent in France and England. A certain number of scientists followed the older nomenclature and insisted that on historical grounds it should be universally adopted. After some controversy the matter was referred to representative committees of the American Association of Immunologists, the Society of American Bacteriologists and the Association of Pathologists and Bacteriologists. They have investigated the subject and have recently presented their report (*Jour. Amer. Med. Assn.*, 1921, lxxvi, 130). They recommend: "As further confusion and the possibility of accident may be avoided by the universal use of one classification, it is recommended unanimously on the basis of priority that the Jansky classification be adopted." The subject is one of some importance and should receive all possible publicity so that the change may be made as promptly and as generally as possible. The societies named stand at the head of the profession in this country and it may be accepted that whatever they recommend is worthy of acceptance. In this particular instance the reason for their recommendation is obvious and compelling. So let all concerned remember that *group one* is the group of so-called universal donors.

LOVE AS A CAUSE OF DISEASE SYNDROMES.

NICLOT, writing in *Le Progrès Médical* for November 6, 1920, xlviii, 45, gives a résumé of some of the pathological effects of the love passion and classifies them. He begins with an ode by Sappho which expresses paroxysmal passion. The effect of the smile of the beloved is to cause the heart of the lover to palpitate, he or she becomes voiceless, can no longer see, the ears ring, one becomes

covered with cold sweat, trembles from head to foot, and feels about to die. This syndrome was followed more or less closely by the successors of Sappho with now and then some addition; thus one of Theocritus's heroines becomes cataleptic. Several poets mention a deep reddening of the entire surface, a blush as if from deep shame. So much for critical paroxysms.

Niclot next takes up "consumptive" love. The victim of the passion is believed to be under the influence of the evil eye of some offended deity. Certain love philters could produce the same effects. The subject is obsessed with love or, as we say today, bewitched. Being in this condition the victims are ripe for great crimes. This kind of love may be instantaneous in its inception but requires much time to wear off. It is the ordinary love-sickness. The liver was believed to be the organ which bore the brunt of the disease although the poets mentioned only the heart. Some of the more analytical spoke of love as magnified and illogical desire, more or less morbid. The highest morbidity was seen of course in incestuous loves. This passion could naturally be conceived of only as the work of offended deities or magic.

The physical consequences of this life in the victim are dwelt upon. He may according to Theocritus, fast for days until he becomes skin and bone; this of course when his passion meets with insuperable obstacles. "Love, thou hast drank the last of my blood like the leeches of the swamps," exclaims one. Seneca gives a detailed account of the syndromes as follows: emaciation, progressive breaking down of forces, refusal of food, insomnia, tears, pallor, photophobia, and instability in purpose and desire. Another states that love as far as the mental state went was a form of drunkenness. Falling of the hair is mentioned by Theocritus. Erasistratus gives an account of the consequences of masked or hidden love. These comprised languishing eyes, with anomalies of the voice and complexion, tears, etc. When a patient presented these symptoms, especially if he or she were a youth, the medical man should suspect a secret love passion. The source of the latter might be found by the reaction which took place on the entrance into the room of the object of the passion. This consisted of a change of color, trembling, palpitating and sweating. The astute physician by placing his hand over the subject's heart could feel its agitation when the object of love entered the room. Plutarch mentions the behavior of Antiochus as comprising all of the Sappho syndrome. He was cured by the only method—that of procuring for him the desired woman, who chanced to be the wife of a fellow monarch. In later years the pulse was deemed a sufficient guide for the medical man, the other symptoms having been regarded as largely secondary to the disturbance of the heart.

APPENDICULAR ASTHMA.

GUTMANN, writing in the *Presse Médicale* for November 3, 1920, xxviii, 80, describes an asthma motivated by chronic appendicitis. He relates a

case in point in which a young woman appeared with the complaint of asthmatic attacks dependent apparently on indigestion. The radioscopic examination showed a fixed cecum, and induced tenderness was obtained over the area. Operation revealed chronic appendicitis with posterior adhesions. The asthmatic attacks did not reappear. During the war the author saw several similar cases in soldiers. Another case is given in great detail. The patient was a young woman with frequently repeated crises of asthma, preceded, however, by vague colicky pains. No evidence of anaphylaxis could be found. An attack of influenza did not alter the course of the disease. Drug treatment gave hardly any relief and the one or more daily attacks could not be permanently influenced. The personal history made it likely that the patient had had an acute appendicitis some time before the first asthmatic crisis, but the evidences of chronic appendicitis were dubious until an x-ray picture was taken and showed the cecum in the pelvis. Having located the exact position of the appendix, not only was a tender pressure point found, but it was possible by palpating the tender point to bring on a crisis of asthma at will. A much inflamed appendix was removed and the asthma ceased. The author believes that fixation of the cecum may have importance in causing reflex manifestations when there is chronic inflammation of the appendix. In regard to producing asthmatic crises at will by "pushing a button" it must be remembered that the bell does not ring unless the battery is charged, and that vagotonia may take the place of the "charged battery" in the simile.

THE MEDICAL STUDENT SINCE THE WAR.

THE opening of a restaurant for the University medical students of Paris moves the editor of *Le Bulletin Médical* for December 8-11, xxiv, 59, to discuss the alleged loss of gaiety of student life since the war. The restaurant, besides making an economic appeal, is believed to favor fellowship. While it is to be doubted that youth can change its nature as a result of unusual experience, something is to be said on the other side. The student has lived much in the past few years and has aged physically and morally. He has from another viewpoint lost several years of his life. Some of the younger students did not pass through this ordeal, but it is conceivable that they would be influenced by the behavior of their older comrades. Unless the student of today has a home with his parents he is at a great disadvantage. Even the "hall room" or its French prototype is now quite beyond his means. The ordinary restaurant prices are also beyond his purse, else the new refectory established through the influence of the Faculty would not have been heard of. Text-books are 100 per cent. dearer and scarce at that. The bourgeois parents, who for three centuries "have furnished France with brain cells," hesitate today to finance their son through his medical undergraduate course. It means an expense of 10,000 to 12,000 francs annually for five or six years, and this applies not only to the medical but to the law, teaching, and art professions. And suppose there is not only one but two, three, or more boys to provide for. Perhaps

only the profiteer and other new rich will have sons who are professional men. The laboratories are in peril, for the disinterested student who loves science for its own sake is too poor to spend his time without material compensation. For the same reason there is a great shortage of teachers.

HOW TO TELL WHETHER A YOUNG CHILD SQUINTS.

CANTONNET states that at first thought nothing seems more evident than a squint (*Le Progrès Médical*, November 27, 1920, xlviii, 48). But in the case of an alleged squinting infant, some one will assure the practitioner that the child squints constantly, some other relative is equally certain that the squint is only occasional, and finally there will be some one else who will testify that no squint is ever present. When the child is old enough to recognize diplopia as a subjective experience we have a check on the objective finds; but before this period we must rely on some objective test to check up the seeming squint, which may of course be of the alternating or transitory type. The practitioner sits facing the infant with the light on the latter's face and "blinds" each eye in succession. An ordinary visiting card makes a satisfactory blind. One eye being covered the infant is made to gaze at the examiner and after two or three seconds the card is quickly shifted to the other eye, and again the child is asked or made to gaze directly in the examiner's face. If there is no squint the eyes remain fixed as the card is moved from side to side. Both are directed at a fixed point and good binocular vision is assured. The shutting off of vision by the card does not affect this fixation. But even if the squint is latent or slight it will be unmasked by this maneuver. The presence of the card may be followed by fixation on the part of one eye while the other diverges or converges. If the eye shifts toward the nose, then the examiner quickly transfers the card to the other eye; whereupon the first eye redresses itself while the second in turn converges. In another maneuver the child is made to look at a lighted candle at a distance of 80 cm., the observer's eyes being in the same line with the light and the eyes of the subject. Bright points are now visible on the corneæ of the latter, and according to the position we are able to tell whether binocular vision is normal and the kind and degree of squint, if abnormal.

News of the Week.

Measure for Immediate Relief of Disabled Soldiers and Sailors.—An amendment to the Sundry Civil bill appropriating \$30,000,000 for the immediate relief of wounded and disabled American soldiers was introduced into the United States Senate on February 3 by Senator Robinson of Arkansas. He charges Congress and the Government with continued failure to provide proper hospitalization for disabled veterans of the world war and fears the present session of Congress will pass without due provision for this urgent need. Under the Robinson amendment \$15,000,000 would be available immediately and \$15,000,000 on July 1, 1921. Senator Smoot states that the Committee on Appropriations is able to report \$12,500,000 for the relief of sick and disabled soldiers, but Sena-

tor Robinson claims that the Public Health Service estimates that \$30,000,000 is urgently needed immediately for hospital care of disabled war veterans.

Bills Relating to Mental Defectives.—Bills designed to perfect the law concerning the care and treatment of mentally defective children have been introduced into the New York State Legislature by Nathan Straus, Jr. Under the laws proposed examination of a mentally defective child may be made either by two qualified physicians or by a competent physician and a psychologist. One of these measures provides that a magistrate may commit a child either before or after trial to a hospital or "other suitable place" for a period not exceeding ten days for observation and examination as to mentality. The bills have the support of the Department of Public Welfare of New York City.

Cut Alcohol in Patent Medicines.—Prohibition officers are preparing to take the first step to stop the manufacture of intoxicating beverages masquerading as patent medicines. Where such beverages are found to violate the Volstead act permits for the manufacturers to withdraw alcohol from bonded warehouses will be withdrawn. A number of preparations which have appeared on the market since national prohibition came to pass have been analyzed by officials and found to be intoxicating beverages within the meaning of the law. Many others are being examined.

Encephalitis Lethargica in Boston.—During the month of January, according to Health Commissioner Woodward, sleeping sickness has caused five deaths and thirteen other persons have been prostrated by it in the city of Boston.

Automobile Accidents Increase in New York.—Automobile accidents during the month of January, 1921, were 90 per cent. more frequent than during January, 1920. The National Highways Protective Society reports that 55 persons were killed by automobiles, 10 by trolley cars, and two by wagons. In the State, including the city, there were 88 deaths by automobiles. The great increase in the number of accidents in January, 1921, as compared to those in January, 1920, is to a considerable extent accounted for by the fact that during January, 1920, the roads were practically impassable owing to heavy snow storms.

New Jersey Passes Maternity Bill.—The New Jersey House of Representatives has passed the Whitney bill providing for a commission to consider legislation restricting the employment of women for periods before and after childbirth and of legislation providing for maternity benefits.

Typhus Suspects on Italian Liner.—Four typhus suspects were discovered aboard the Italian liner *President Wilson*, which arrived in the Port of New York on February 1. These patients were removed to the Long Island College Hospital, but later sent back to the vessel. In view of the gravity of the discovery Health Commissioner Copeland stated that the Health Department would not permit any of the 1,400 steerage passengers on the *President Wilson* to land until all danger was passed. A follow-up of the cabin passengers

who were allowed to land has led to the discovery that one of these has typhus fever and in being treated in Willard Parker Hospital.

City-Owned Hospital for Bronx.—At a public hearing held in City Hall on January 21, 1921, the Board of Estimate and Apportionment recommended the application of the Bronx County Medical Society to erect a city-owned hospital for the Borough of the Bronx. The board referred the selection of site and manner of financing the proposed hospital to the Committee of Finance and Budget.

Fewer Physicians Prescribing Whiskey.—According to a statement issued by Wayne B. Wheeler, general counsel of the Anti-Saloon League, only 22 per cent. of the physicians of this country are holding permits to prescribe whiskey, while 78 per cent. hold no permits. There are, according to Mr. Wheeler, twenty-four States in which physicians hold no permits to prescribe liquor and druggists cannot fill prescriptions for whiskey or brandy. These States are Alabama, Arizona, Arkansas, Delaware, Florida, Georgia, Idaho, Indiana, Kansas, Maine, Mississippi, Montana, Nebraska, Nevada, New Mexico, North Carolina, North Dakota, Oklahoma, South Carolina, Oregon, Tennessee, Utah, Washington, and West Virginia. It is of little use for a physician to take the trouble to secure a permit which limits the dose to a pint of whiskey in ten days.

Asks Daylight Saving to Ward Off Disease.—The Health Commissioner of New York City appeared before the New York State Legislature on February 2 to urge the retention of the Daylight Saving law. He contended that there never was a time in the history of the United States when the lives of the people were endangered as they are to-day when they are threatened by the plagues that are rampant in Europe and are living in more over-crowded conditions than ever before. He believes the additional hour of sunlight and daylight conferred by the Daylight Saving law is most important at this time to the health of city dwellers and more particularly of the tenement house mothers and babies.

Dies at Age of 111 Years.—Joseph Mantell died in Toronto on February 1 at the age of 111 years. He was born in England and came to Canada eighty-two years ago.

Dr. Wilder G. Penfield of Princeton, N. J., has received a Beit scholarship. He will make researches in the pathological development of medical science in England during the coming year.

Dr. Samuel N. Clark, for seven years psychiatrist to the Illinois State Psychopathic Institute, has been appointed psychiatrist to the Norbury Sanatorium, Jacksonville, Ill.

Positions Open to Physicians.—The Civil Service Commission of the State of New York announces the following vacancies in the following positions for which no written examinations will be required, but candidates will be rated on training, experience, and qualifications: (1) Supervisor of Child Hygiene, State Department of Health, at a salary of \$3,000. The duties of the position require a thorough knowledge of and training in children's diseases. (2) Assistant Medical Officer,

Office of Health Officer, Port of New York, at a salary of \$1,800. The appointee must reside at City Island and give part of his time to the inspection of vessels from foreign ports and the inspection of passengers. (3) Assistant Resident Physician, New York Training School for Girls, Hudson, N. Y., at a salary of \$1,680 and maintenance. Applicants must be licensed physicians graduated from a registered medical school, but need not be residents of New York State. Applications will be received at the Civil Service Commission, Albany, N. Y., up to February 19, 1921.

The Medical Society of the State of New York will hold its annual meeting in the Borough of Brooklyn, May 2, 3, 4, and 5, 1921. In connection with this meeting a public health exhibition will be held in the Twenty-third Regiment Armory. In addition to the regular exhibits there will be a section devoted to the public (which will be admitted free) wherein the various health and labor-saving devices commonly used will be presented. The committee in charge of the exhibit plans to secure the cooperation of the dentist and the pharmacist, and in a series of educational exhibits and addresses to cover the public health question in its broadest sense.

Vacancies for Biologists and Psychologists.—The United States Civil Service Commission announces an open competitive examination for biologist to fill two vacancies in the Hygienic Laboratory, Public Health Service, Washington, D. C., at \$2,500 to \$3,000 a year, and vacancies in positions requiring similar qualifications. Applicants must have received the degree of Ph.D. from a university of recognized standing and must have had thorough training in biology, bacteriology, chemistry, and physiology. An open competitive examination for psychologist to fill vacancies in the Public Health Service throughout the United States, at \$1,600 with maintenance, or \$2,200 without maintenance, is also announced. Applicants must have graduated from a college or university of recognized standing, with major work in social science or psychology, and must have had three months' experience in work involving normal psychology. Applicants for these positions should apply for Form 1312, stating the title of the examination desired, to the United States Civil Service Commission, Washington, D. C. All applications must be filed with the Civil Service Commission before March 15, 1921.

Smuggled Cocaine Seized.—In examining baggage belonging to the steerage passengers on the Fabre liner *Patria*, Thomas E. Rush, Surveyor of the Port, found 300 bottles of cocaine valued at \$10,000 concealed in a false-bottomed trunk. According to figures given out by Dr. Carleton Simon there were more than 280 arrests in the anti-drug crusade during the month of January.

Red Cross Relief Plan for New York.—The Red Cross Disaster Relief Committee, in cooperation with the New York Police and Fire departments, has worked out plans which will make it possible to get a large quantity of first aid supplies quickly to any point within the metropolitan area where a disaster may occur. First aid boxes have been placed at the headquarters of eighteen in-

spection districts of the city, and arrangements have been made for the Police and Fire departments to notify the committee immediately of any occurrence demanding their attention. A complete survey has been made by the committee of the resources that would be available for relief in the various communities that compose the metropolitan district. In the event of disaster the mayors of cities, presidents of villages, and police and fire officials will notify the committee immediately. The Fire Department of this city has established a special fire alarm telegraph call for the Red Cross unity.

Obituary Notes.—Dr. GEORGE T. STEVENS, formerly professor of physiology and diseases of the eye in Union College, and a practising physician in New York City since 1881, died at his home on January 30, at the age of eighty-eight years. He was a graduate of Castleton Medical College in 1857, a member of the Loyal Legion, and many scientific societies. He devised a number of surgical instruments for use in the treatment of diseases of the eye that have become standard. He was awarded a prize by the Royal Academy of Belgium, in 1883, for a treatise on nervous affections.

Dr. LOUIS C. PURMAN, a graduate of Howard University School of Medicine, 1884, died at his home in Washington on January 26.

Dr. HENRY HARRINGTON JANEWAY of New York and Riverdale, a graduate of the College of Physicians and Surgeons, in 1898, died at his home in Riverdale, on February 1, at the age of forty-eight years. He was a member of the American Medical Association, the American Association for Cancer Research and the New York Academy of Medicine. He was attending surgeon at the Memorial Hospital.

LIEUTENANT E. S. TAYLOR, a naval officer, was shot and instantly killed by a sentry at the naval operating base at Norfolk, Va., on January 30. Lieut. Taylor was twenty-eight years of age and a native of Greenville, N. C.

Dr. CHESTER C. BECKLY of Lancaster, Mass., a graduate of the University of Vermont Medical College, in 1898, died after a week's illness, on February 4, at the age of forty-six years. He was a Major in the Medical Corps of the army during the war, serving in camps in this country and at the front in France.

Correspondence.

THYROID PREPARATIONS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Having been using thyroid in the treatment of myxedema and allied conditions constantly since 1893, and having had several individuals under my observation continuously during all that time, and many for several consecutive years, I have reached certain conclusions regarding the effects of the various preparations of thyroid which should be made known to the profession.

During 1893 Dr. George W. Cray obtained the fresh thyroid glands of sheep and prepared a glycerine extract from them, which he kept on ice, and furnished my patients. The dose of this was arbitrarily fixed by us at 10 minims, which had to be

varied in different cases from 10 up to 35 minims t.i.d. Later on tablets and capsules were put on the market by different druggists and these were all tried on patients and found to be of very uncertain strength and to have various effects. Finally I settled upon the Burroughs & Welcome preparations as the most reliable and uniform in strength and have so stated in my books and articles, but these were not always satisfactory—the thyroid extract which was prepared from lambs or from sheep in the springtime was always much stronger than that obtained in the winter. And some preparations—though carefully kept cool—appeared to deteriorate more easily than others and to have certain unfortunate results. Thus severe nausea, very rapid pulse, mental depression, peculiar eruptions, sometimes purulent, sometimes like psoriasis, and even febrile states would develop from time to time in patients who were taking the tablets regularly—with no apparent reason, and without relation to their myxedema. That these effects were due to the thyroid preparation was proven by the fact that each of these symptoms would in turn disappear when the medication was stopped for a time. Several very intelligent patients who could watch these effects closely soon became accustomed to get a new supply of the tablets as soon as an unfortunate set of symptoms developed, insisting on a fresh preparation, or trying for a time some other extract in place of the tablets they had been using. Eventually all came back, however, to these tablets as being more free from impurities and as giving better results. During the past year, however, a preparation made at the Cornell University Medical College laboratory, has been available; which is named 5 per cent sheep thyroid nucleoprotein tablets; and which I have found to be free from every unfavorable result in use. The exact strength of this as expressed in grains of thyroid extract of Burroughs & Welcome is uncertain; but I find that 1 tablet produces the same result as a 1 grain tablet of the latter preparation. For many years I have been accustomed to prescribe thyroid in small doses frequently repeated— $\frac{1}{2}$ grain or 1 grain every hour or two hours—being better borne than a large dose three times a day. Nature furnishes thyroid steadily to the blood and her method should be followed. I have tried all the so-called substitutes for thyroid—iodothyrene and many other forms, and believe that no preparation is as satisfactory as the one to be obtained from the Cornell Laboratory—and for this reason I wish to make the facts known.

There is no remedy which is more generally useful in conditions of malnutrition, of anemia, of neurasthenia, of general feebleness, or after recovery from serious diseases which impair the vitality, than thyroid. In advancing years, at the menopause, and in old age it is known that the glandular activity diminishes, and experience has convinced me that a small amount of thyroid two or three times a day is of great service. I also believe that it acts in a way to protect the system from the inroad of infectious diseases. It is to me very remarkable that my myxedematous patients have so uniformly escaped infectious colds, catarrhal conditions, and the grippe during all these years. This also is true of patients who have exophthalmic goiter.

For all these reasons it seems important that as the use of thyroid becomes generally appreciated a good reliable preparation should be prescribed.

M. ALLEN STARR, M.D.

5 WEST FIFTY-FOURTH STREET,
NEW YORK.

[It is but just to state that various other preparations than those mentioned by Dr. Starr are now made and have been found reliable by many clinicians.—ED.]

THE NARCOTIC LAW AND A PERSONAL EXPERIENCE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—About two weeks ago I was attacked with synovitis of the right shoulder joint and severe neuritis of the shoulder and upper arm. I did all I could to get relief through my own treatment and with the aid of two best consultants. Finally, I thought it would be useful, with the action of a curative local agent, to paint the very painful region with laudanum. I could not write on account of the pain in my arm, so I requested my druggist of many years to fill out printed applications and allow my acting nurse to sign them for me. This he declined to do, as he said he had not the right without the doctor's order who was in attendance upon me. I had no attending doctor; only an attending consultant, who was out of town, and had no printed forms. It was necessary for me, therefore, to send for a doctor in general practice, who might have the printed forms, to come and see me and then be willing to do as I requested. Fortunately for me, I found my pain had lessened somewhat and I did not do the only effective thing that remained to me.

Now then, conclusion: I am an old practitioner and believe my character and reputation are unblemished and yet I can not have, in dire emergency of extreme pain, a local anodyne, which is a narcotic, to relieve me locally. What is to become of a great and noble profession when limited, controlled in its very essence, by wrong, one-sided laws, the outcome of ignorance and fanaticism beyond thought?

Alas, the shame, the pity, and the crying outrage of it all!

BEVERLEY ROBINSON, M.D.

125 EAST THIRTY-FIFTH STREET,
NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

LONDON, Jan. 14 1921

The Employment of Morphine in Labor.—To ease or minimize the pains of labor by such means as neither to injure the mother nor child is a main object in the conduct of obstetrical cases. The accomplishment of this aim has been attempted in various ways. At a meeting of the Section of Obstetrics and Gynecology of the Royal Society of Medicine held in the house of the Society on January 6 last, Dr. Louise McLroy read a brief communication on the use of morphine in labor. Dr. Louise McLroy was in the Balkans and Near East almost throughout the entire war, first with the Scottish Women's Medical Expedition and afterward for some time holding responsible posts in several hospitals. The communication was

based upon the results of the administration of morphine in obstetrical cases occurring in the officers' wives' section of the 82d General Hospital B. Section, Constantinople. Many Turkish, Greek, and Russian women were also admitted for treatment. Most of the cases were first cases, they were not selected, but morphine was given in complicated cases, as, for example, malpresentations and albuminuria. No vaginal examinations were made except in cases where complications were suspected. No douching of the vagina was carried out. Morphine was administered hypodermically. The initial dose was 1 1/6 grain and repeated doses of from 1 1/6 to 1/4 grain were given at varying intervals throughout labor according to the condition of the patient and her capacity for bearing pain. No excitement nor mental confusion was observed, the patients slept at intervals and awakened refreshed. After some experience of the effect of the drug, it was given with the primary object, not of allaying pain, but of shortening labor. Thirst was increased, restlessness was diminished, the third stage was unaffected, and no risks were apparent with regard to the child. No post-partum hemorrhage was observed, less fatigue and absence of shock caused a favorable convalescence after labor. Moreover, the constant attendance of the medical practitioner was not required, as in the administration of scopolamine-morphine. Dr. McLroy, as the outcome of her experience, concluded that the results of the administration of morphine in labor were satisfactory and made of this drug a useful remedy in the management of labor. It helped to bring labor nearer to normal physiological conditions. Dr. Herbert Williamson did not agree with Dr. McLroy with respect to the absence of effect of the drug on the child. According to his experience, if the drug were given two or three hours before the birth of the child, the latter was born in the condition known as oligo-orthopnea. If left alone, it generally came round all right. Dr. McLroy's patients were mostly neurotic women of Eastern or Russian origin, and it could not be too strongly insisted upon that the repeated administration of powerful drugs as a routine measure was neither necessary nor advisable in ordinary healthy women. Dr. Laphorn Smith, from a large experience in attending Russian women, agreed with Dr. McLroy as to their nervousness, and for many years in such cases and in all cases of primiparae, it was his practice to prescribe a mixture with 30 grains of sodium bromide and 1/4 grain of morphine to the dose, to be given as soon as labor began and repeated hourly for four hours. Nurses had called his attention to the excellent condition of patients after labor in these cases. He laid especial stress upon the importance of not making vaginal examinations during labor except with gloved hands.

The Cost of Health Services.—There has been in England and Wales recently a great deal of criticism leveled at the Ministry of Health on account of the cost of their undertakings and proposed schemes. Dr. Addison, the Minister of Health, speaking at a political meeting the other night, said that he had appointed a number of

gentlemen to obtain the true facts of the situation. All the new health services put together, including construction of roads and houses, extensions of hospitals, sanatoriums, services of child welfare, diagnosis and treatment of venereal disease, provision of plant for removal of house refuse and other items amounted to under five pennies in the pound. As to the cost to the Exchequer, the total in the Budget for maternity and child welfare services for England and Wales was £1,000,000, or one-fifth of a penny in the pound. The physical condition of the next generation was fairly indicated in the health of infancy, and in 1920, after this service began to take effect, the infant death rate fell to 77, the lowest previously having been 93 in 1917. It would be false economy to stop that expenditure and he was not going to do it. There can be little doubt that money expended on health services is money well spent, and the reduction of the infant death rate is convincing evidence that the money spent in that direction was the best investment possible.

Alcohol and Industrial Efficiency.—The question of the effect that alcohol exerts on the capacity for work, whether it be what is generally termed brain work or manual work, is of the first interest. It is especially so at the present time when the world, or at any rate a part of it, is settling down to industrial competition, and America has prohibition in force. In Great Britain, the hours during which alcoholic beverages can be obtained are limited and yet a very considerable amount of alcohol is consumed. True it is that inebriating drinks of every description are dearer by far than formerly and less heady, but taking all these facts into consideration a great deal of alcohol is imbibed. Medical men in this country are asking whether the British workmen, in these circumstances, can hope to compete successfully with the American workmen, who presumably do not indulge in alcohol for the reason they are unable to obtain it. Even granting that they can obtain a certain amount, they cannot procure it at the cost and with the facility allowed to their brethren here. At a meeting of the Society for the Study of Inebriety held January 11, Dr. H. M. Vernon opened a discussion on alcohol and industrial efficiency. He pointed out that it was easier to investigate the effects of alcohol on the efficiency of manual workers than on that of the non-manual, but the conclusions arrived at concerning the importance of the physiological regulation of the conditions of drinking in the former class applied equally to all workers. The effects of alcohol on typewriting were systematically studied, as this is a class of work in which accuracy and speed can be easily measured. The subjects of experiment typed a memorized passage at frequent intervals before and after drinking the alcoholic liquid, and it was found that in each of the seven subjects the adverse effect of the alcohol was about twice greater when it was taken three and a quarter hours after food, or on an empty stomach, than when it was taken with food. In another series of experiments Dr. Vernon drank whisky containing $1\frac{1}{2}$ ounces of alcohol at various periods after a substantial meal had been eaten. He found that while the effect produced was com-

paratively slight up to two hours after food, it then underwent a sudden jump, and three and a half hours after food the effect was increased to more than double. With more prolonged fasting, up to 20 hours, the effect became greater still. When vigorous exercise was taken at the end of a 13-hour fast the effect of alcohol was the greatest of all, and for a few minutes induced a condition not far removed from intoxication. Conditions similar to the experimental ones described were sometimes observed in industrial workers before the war when they worked hard for two or three hours in the early morning on an empty stomach and in the breakfast interval visited the public houses, then open at 5 to 8 A. M., before eating food. With regard to the toxicity of beers, a very important point, Vernon found that dilution had a much more than proportionate effect in reducing toxicity. For example, 90 c.c. of alcohol taken in the form of 3 per cent. beer produced only as much effect as 46 c.c. of alcohol in the form of 5 per cent. beer. The speaker was of the opinion that it was practically impossible to become intoxicated on beer containing only 3 per cent. of alcohol. This view was strengthened by the state of affairs in Denmark, in which country the Government allows beer containing 2.6 per cent. by volume of alcohol to be produced and sold free of all taxation, though the stronger beers are taxed and are therefore more expensive. Vernon held that it would greatly encourage sobriety if a scheme of graduated taxation of beers of different gravity were adopted by the Government of this country. It may be said that in Denmark intoxication has almost ceased. In accordance with previous results, the speaker found that the toxic effects of whisky reached their maximum at 10 per cent. alcoholic strength, by volume, and at this concentration they were just as great as that of neat whisky 15 to 50° under proof. Consequently, spirit drinkers by diluting their spirits moderately would reduce the injurious action on the gastric mucous membrane without diminishing the alcohol sensation they desired. The typewriting method showed that alcohol disappeared from the human body at about the same slow rate as Mellanby found it to disappear in the dog. In Vernon's own case it was got rid of at the rate of about 13 c.c. per hour, that is, nearly half an ounce. As one pint of fairly heavy beer contained an ounce of alcohol, it followed that if a man drank a pint every two hours, as was observed in Great Britain during the day time in some industrial drinkers before the war, his blood was never free from alcohol. In the discussion that followed Mr. Nicholson said that prohibition, whatever its merits, was looked upon as a class measure by the laboring man, and Mr. Theodore Neild further said that an attempt was being made in America to eliminate the saloon without stopping the sale of liquor. The conclusions of this meeting were practically identical with those held by the large majority of investigators, that alcohol beyond a certain amount detracts from industrial efficiency. It must be borne in mind that the British workman has always been accustomed to a heavy beer and the gist of the discussion was to the effect that

he should be influenced to drink a low-gravity beer by means of a graduated taxation of beers of different gravity. It had been successful in Denmark, so why not in this country?

Honor for Medical Man.—Sir Edward Napier Burnett, K.B.E., the well known Director of Hospital Services, British Red Cross Society, has been appointed a Knight of Grace of the Order of St. John of Jerusalem. Sir Napier Burnett has a thorough knowledge of the hospital situation in Great Britain and has suggested practical schemes for the reorganization of the hospital system here.

Self-Disinfection in Venereal Disease.—Sir Arbuthnot Lane, Sir Humphry Rolleston, Sir F. W. Mott, and Sir G. Sims Woodhead have been appointed by the National Birth Rate Commission, members of a committee to inquire into various questions in relation to the subject of self-disinfection in venereal disease. All the above distinguished members of the medical profession are advocates of early self-disinfection, and believe that facilities should be provided for carrying this preventive measure into effect.

Obituary.—Dr. T. W. Simpson, one of the physicians to the Royal Hospital for Sick Children, Edinburgh, died very suddenly on Jan. 11. Simpson was an authority on children's diseases and the author of a work on infant feeding, as well as of other books on the diseases of children. He was also one of the greatest athletes of his day, taking part in no fewer than thirteen International Rugby matches. He also shone at golf and was a keen fisherman. Like most men of his type, he was modest and unassuming to a degree, and also like most men of his disposition he had hosts of friends.

Mr. Charles Higgins, F.R.C.S. England, Consulting Ophthalmic Surgeon to Guy's Hospital, died suddenly on Dec. 28. He was 74 years of age and became senior ophthalmic surgeon to Guy's Hospital in 1883, and lecturer on ophthalmology in the medical school. He was also for many years ophthalmic surgeon to the French Hospital and surgeon to the County of London War Hospital during the war.

Progress of Medical Science.

British Medical and Surgical Journal.

January 27, 1921, cxxxiv. 4.

1. "Megacolon." W. E. Ladd.
2. Megacolon in the Adult. Peer P. Johnson.
3. Conditions in Palestine During the War. Izak Alcazar.
4. Recent Progress in Surgery. Edward H. Risley.

1. "Megacolon."—W. E. Ladd prefers the term used to any of the others by which this condition is indicated—"giant colon," "Hirschsprung's disease," "neuropathic dilatation and hypertrophy of the colon," "congenital ideopathic dilatation of the colon"—considering the term "megacolon" quite satisfactory, providing it is not confused with pseudomegacolon, a disease of the adult. Broadly speaking, megacolon may be said to be a disease of childhood only, though it is possible that occasionally a patient may reach adult life with this condition. Its congenital origin seems well established, as several cases have been reported during the first few days after birth, and at least one in a seven months fetus. The cause is still a matter of speculation. Pathological findings show an enormously dilated and hypertrophied colon, the affected part beginning and

ending abruptly, the sigmoid and descending colon being the portions most commonly involved, though occasionally one sees the whole colon, from the rectum to the cecum, enlarged. The small bowel is not involved, and does not become distended even when the colon has tremendous fecal retention. In all the writer's cases the mesocolon has been unduly long and without the extreme thickness mentioned by others. The intestinal wall of the affected portion is two or three times thicker than that of the unaffected gut. Clinically the story is usually one of constipation from birth or soon afterwards, the most important feature of the constipation being the long periods of time—several days, or even weeks—in which there is no bowel movement without evidence of acute obstruction. Sometimes the bowels may move daily when there is still tremendous fecal retention. The diagnosis should always be confirmed by a radiograph of a bismuth clyster. No treatment, medical or surgical, is always successful. The two operations which the writer considers worthy of consideration are colostomy and resection of the affected colon with anastomosis between the normal gut above and the lower sigmoid below. Partial colectomy with anastomosis is the operation of choice and the one that yields the best hope of success. Ladd reports five cases which, with 113 collected from the literature, make 118, 60 of which were treated medically, with 41 deaths, a mortality of 67 per cent.; 4 unimproved, 6 per cent.; 8 improved, 13 per cent.; 7 cured, 12 per cent. Of the 58 surgically treated, 24 died, a mortality of 41 per cent.; 2 were unimproved, 3 per cent.; 8 were improved, 14 per cent.; 24 were cured, 41 per cent. From these figures it would appear that the chance of curing a patient by the surgical treatment is over three times as good as by the medical treatment.

2. Treatment of Addiction Disease.—Frank Burns reports on his work as Federal physician for the southern district of Ohio, in which capacity he has devoted a great deal of time to the medical handling of drug addiction disease patients, arrested in this district by narcotic officials. The series includes eighty-four males and nine females, a total of ninety-three. From his observations he draws the following conclusions: 1. Lipoidal substances gradually reduce the craving. 2. During the treatment with lipoidal substances the patient does not suffer the tortures experienced during the reduction treatment. 3. All the by-symptoms of drug addiction disease (respiration, heart action, constipation) are rendered normal during the treatment with lipoidal substance. 4. In patients once clinically recovered under the influence of lipoidal substances there develops a well-defined contempt toward alkaloids. 5. Patients with pathological changes not due to the influence of alkaloids will go back to the use of narcotics. 6. Patients who suffer solely from the ill effects of alkaloids will remain normal, once the treatment comes to a successful conclusion. 7. Lipoidal substances are administered hypodermically with no ill effects whatever.

3. The Role of the Ocular Muscles.—Edwin B. Miller, considering the subject from an economic and social point of view, holds that the study of muscle imbalance and the search for these cases is the duty not only of

the specialist, but also of the general practitioner. The correction of these errors is a boon to many suffering patients, and opens up a new world to them, from both economic and social viewpoints. The recognition of these conditions, and the knowledge that they can be greatly improved or entirely cured by suitable measures, should be disseminated throughout the community. The utmost frankness and cooperation should exist between the employer of labor, the teacher, the physician, and the parents of the child.

9. **The Renorenal Reflex.**—Wilbur H. Haines and K. P. A. Taylor report a case in point, and assert that modern methods of diagnosis have not refuted the renorenal reflex. Cases such as the one reported point rather to the importance of careful cystoscopic and roentgen-ray study of all suspected surgical kidney cases, and the neglect of such study prior to operation could only justify the accusation of negligence. Disease of the healthy kidney as well as disease of the corresponding genitourinary tract must be eliminated before a diagnosis of renorenal reflex can be made. The reflex is easily explainable on anatomical grounds, but its exciting cause is not understood.

4. **The Treatment of Pernicious Anemia by Splenectomy.**—Giffin and Szlapka make this second report, which they consider of value chiefly as a statement of the postoperative life of the fifty patients operated on more than three years ago. The operative mortality was 6 per cent. Ten patients (21.3 per cent.) of those who recovered from operation survived splenectomy three years or longer. Five patients (10.6 per cent.) of those who recovered from operation have survived splenectomy more than four and one-half years, and are still living. The total length of history of these five patients averages almost six years. It may be said with reasonable accuracy that, in addition to the immediate remission which occurred constantly following splenectomy, splenectomy prolonged life in at least 20 per cent. of the cases. The writers cannot satisfy themselves that any particular preoperative characteristics of the disease are indicative of favorable results following splenectomy. However, in the type of case in which there is evidence of active hemolysis, the patient shows a more marked immediate improvement. Splenectomy may be recommended in pernicious anemia when, in view of all the circumstances, personal as well as medical, the possibility of the prolongation of life appeals to the family and to the patient. Occasionally the operation may be performed in order to bring about an immediate remission.

5. **The Relationship of High Blood Sugar to Furunculosis.**—William Thalheimer reports the case of a school-boy, aged 15, whose history is deemed sufficiently important to record because (1) the original complaint was of "attacks of multiple furuncles," and in investigating this condition it was discovered that the patient had a high blood sugar, and (2) the clue given by the high blood sugar was investigated further, and it is believed

that the data indicate that this is a case in either the prediabetic stage, or else an unusually early stage of diabetes. It has been impossible to reach a definite conclusion as to just what is the underlying condition in this case. One of the main points of interest is the apparent relationship between the high blood sugar and furunculosis in a case which is not one of outspoken diabetes. The most conservative opinion would be that this case shows an abnormal carbohydrate metabolism, which is so nearly the same as that in diabetes that it may be called a prediabetic stage of this disease. It may be, however, that the case is an extremely early one of diabetes. It was noted by the boy's parents that before the attacks of furunculosis appeared he was in the habit of eating tremendous quantities of carbohydrates. This indulgence in large amounts of carbohydrates might signify that the diabetic condition or tendency of the boy caused this appetite for carbohydrates. It is possible that he indulged excessively in carbohydrates and that this precipitated the furunculosis and the abnormality in carbohydrate metabolism.

9. **Menthol and Peppermint in Acute Catarrhal Conditions of the Respiratory Tract.**—Hugh McGuigan tested the effect of menthol or oil of peppermint on surface viscosity. With a suction filter pump he drew a current of air through solutions of soap, blood, saliva, and saponin. Each of these, especially the soap, saponin, and blood, foam readily. The merest trace of menthol or spirit of peppermint added to these solutions rapidly destroys the foam. Crystals of menthol may be added apparently without much effect. The foam in such conditions is so strong that it readily supports the crystals, and to be effective the drug must be in solution or in a condition in which volatility can act. Menthol, however, dissolved in saliva has a noticeable effect, and in alcohol the effect is still stronger, because of greater solubility. In another experiment in which a dog was anesthetized with ether through the trachea by means of a tracheal cannula, marked râles developed. Râles develop frequently in such cases. A few drops of the spirit of peppermint in the tracheal cannula immediately broke the foam and noticeably relieved respiration. There is, therefore, a reasonable basis for the statement that the efficacy of menthol and peppermint in the respiratory passages is due to the changes in the surface viscosity of the mucus and on the membranes producing the exudate. An important and well-established fact in viscosity is that the viscosity of a liquid is increased about 2 per cent. for each degree that the temperature is lowered. This is of great importance in the treatment of all respiratory cases in which the expulsion of mucus is desired. Warm, moist, inspired air will greatly aid the expulsion, while cold air, if respired, will increase the difficulty. What has been said of menthol and peppermint undoubtedly can be extended to other substances of this general class.

9. Ostelut Deformans. Frank Romer. With Observations by Sir W. Arbuthnot Lane.

1. **An Address on the Use and Misuse of the Curette.**—W. E. Pothergill, in summarizing his views on this subject, emphasizes the point that the curette is mainly a diagnostic instrument. Apart from mere increase in the duration or quantity of the menstrual flow, and in the presence of any uterine hemorrhage whose cause is not clear, the rule, "When in doubt, curette," is a sound one. In women of reproductive age the cause of irregular bleeding is found in the majority of cases to be

retained products of conception; and it is remarkable how often these relics are found in women who will not admit that they have missed a single period. Sometimes one or more polypi are found. Occasionally, though the cervix feels normal, the curette finds a place within the cervical canal where epithelioma yields like cheese. And not so very rarely malignant disease is found within the body of the uterus. After the close of reproductive life uterine bleeding absolutely demands dilatation and exploration by curette unless the hemorrhage has an obvious cause, such as cancer of the cervix, the twisting of the pedicle of an ovarian cyst, or the degeneration of a fibroid. In these postmenopausal cases exploration generally reveals the presence of cancer of the body of the uterus; but sometimes there is nothing but the result of a chronic infection whose steps are senile vulvitis, vaginitis, cervicitis, endometritis. In these cases, if the cervical canal becomes occluded after the endometrium has been infected, the result is pyometra, with distension of the uterus by pus and blood-stained purulent vaginal discharge. In cancer of the corpus uteri infection of the ulcerated new growth occurs very late, so that the discharge becomes offensive only when the disease is far advanced. Thus foul discharge means pyometra, or late cancer of the body, while a discharge of pure blood through a clean vagina means early cancer of the body. The cases of senile hemorrhagic endometritis and of pyometra are more numerous than is realized, and they are quite curable by the curette. Thus the operator who removes every enlarged bleeding uterus in an old patient without preliminary exploration will subject to the discomforts and risks of hysterectomy a certain proportion of old ladies who could have been cured by a simpler and safer method.

6. **Diabetes Insipidus Complicated by Intermittent Glycosuria.**—Evans and Wallis give the histories of two patients who appear to be examples of a pituitary dystrophy comparable to those clinical cases of thyroid dystrophy in which there is no marked change in the size of the gland and no distinct clinical picture of either hypo- or hyper-function. From their past history neither case seems to be progressive. These patients are not, therefore, regarded as early cases of acromegaly or other recognized pituitary syndrome, but rather as persons in whom the pituitary is functioning irregularly and perhaps at times excessively. We believe that cases of the type here described have not been previously recognized. The two cases are alike in their salient features, and they do not fit into any of the subdivisions into which Cushing divides his five main groups of dyspituitarism. The interest of the cases does not lie in the possibility of their representing a group of dyspituitarism that has hitherto escaped recognition, but depends on the fact that such cases may lead to the recognition of clinical phases of pituitary activity that bridge the gap between physiological and pathological states. When this borderland has been explored the earliest stages of progressive pituitary disorders will be more easily recognized.

2. **Abstract of a Lecture on Subacute Bacterial Endocarditis.**—Basil Parsons-Smith places subacute bacterial endocarditis in a position midway between the simple and the fulminating types of the disease. The onset of the disease is usually insidious, and symptoms are not necessarily pronounced; in fact, more often than not they appear to be extremely vague. Not so the physical signs, which present an unmistakably clear-cut clinical picture. Examination of the heart shows in every instance the presence of an organic murmur at the aortic or mitral regions; apart from the murmur, the heart may show little or no evidence of functional disturbance during the course of the disease; beyond a simple tachycardia the rhythm, as a rule, remains

unaffected, the myocardium retains its power, venous stasis does not develop—in fact, one may follow the entire progress of the disease without noting at any time a full development of the true signs of cardiac failure. In other words, it may be very reasonably concluded that the endocarditis does not represent or explain the signs and symptoms which one has learned to associate with this disease, and furthermore, one can readily understand the prevailing idea of the nature of the malady—namely, that it is a general systemic disease depending upon a bacterial invasion whose seat of origin is localized at some focus of chronic or quiescent valvulitis. A blood culture must be attempted in every case that comes to notice, but a negative result should not deter one from further efforts to cultivate the organism. The writer believes that the variety of endocarditis under consideration is not the result of any one specific organism; several types have been found, including pneumococci, gonococci, the influenza bacillus, and small streptococci. The disease is invariably fatal, from three to twelve months being the average period. The cause of death is cerebral embolism or hemorrhage, uremia, progressive anemia, or intercurrent pneumonia. Treatment should follow the broad lines adopted for any form of septicemia.

4. **Adrenalin in Resuscitation from Apparent Death.**—Cranston Walker reports having injected a minim or two of 1 in 1000 adrenalin chloride directly into the heart muscle in some twenty cases of death from various causes, when all signs of life had ceased for several minutes. A fine needle was passed through the fifth left intercostal space, just mesial to the lung resonance; the point was directed slightly inwards and upwards, and could be felt to enter the apex of the heart; when firmly imbedded in the muscle the injection was made. Several of these needle tracks were examined *post mortem*, and in no case did it appear that any drawback would have ensued had the patient survived. Adrenalin applied to the heart muscle acts on the sympathetic neuromuscular junction, and very greatly increases both the excitability of the tissue and the energy output of the muscular contractions. The writer considers the method sufficiently promising to invite preliminary experiments on animals.

8. The Influence of the Thyroids on the Functions of the Suprarenals. P. T. Herring.

6. **Effects of X-Ray Treatment of the Hypophysis in Bronchial Asthma.**—Ascoli and Fagioli call attention to the fact that hitherto radiotherapy in endocrinology has been used only in destroying tissue, as in cases of exophthalmic goiter, in tumors of the hypophysis, etc. It remained to be seen whether, with lighter applications, the opposite effect could be reached of stimulating the gland cells to activity, or, in other words, if a stimulating endocrine radiotherapy were possible. As soon as the necessary apparatus was available they tried the practical application of the principle suggested, the first case being one of dystrophic adiposo-genitalis, the hypophysis as well as the thyroid being irradiated. Favorable results were obtained in this case, and also in a case of Basedow's disease with two irradiations of the thymus. Results were negative in a typical case of eunuchoidism, a case of angioneurotic edema of Quinke, and three cases of diabetes mellitus. In view of the favorable results obtained by various observers in the use of pituitrin in asthma, irradiations of the hypophysis were tried in five cases of this disease. At each

sitting three different fields were irradiated—one frontal and two temporal—for 12 minutes with aluminum filter of 2 mm. S.E. 13-20 c.m. and $3\frac{1}{2}$ m.m. current. In these five cases the favorable influence of the irradiations is clear. In the othopathic treatment of asthma usually pituitrin and adrenalin are used together; therefore, whenever the stimulation of the hypophysis proves insufficient one should try the stimulating irradiation of the adrenalin also. At any rate, the case reported clearly demonstrates the usefulness of the treatment. Further experience is needed to determine the duration of the application and the persistence of the effects. At the same time, the authors say, one should make sure that the effect is really due to stimulation of the hypophysis or whether there are other factors acting on the syndrome.

8. The Influence of the Thyroids on the Functions of the Suprarenals.—P. T. Herring discusses the effect of hyperthyroidism upon the size, weight and structure of the suprarenals; the effect of hypothyroidism upon the size, weight, and structure of the suprarenals; the effect of hyperthyroidism upon the adrenalin content of the suprarenals; the effect of hypothyroidism upon the adrenalin content of the suprarenals; the effect of hyperthyroidism upon the adrenalin content of the blood; the sensitizing action of thyroid upon structures stimulated by adrenalin; the thyroids and suprarenals as a subsidiary heat-regulating mechanism. The writer summarizes the discussion as follows: There is much evidence, though not unanimous, that hyperthyroidism increases the size and weight of the suprarenals. The observations in this respect are confined to a few species of animals, chiefly the albino rat, and it does not follow that a similar change takes place in all animals. In the albino rat the hypertrophy of the suprarenals is due mainly to an increase in the size of the cortex of the gland, the histological features of which have not as yet been investigated. The hypertrophy of the cortex of the suprarenals is associated with gross changes in other organs and in the general metabolism of the animal, and it is to these influences rather than to a specific action of thyroid that the cause may be attributable. There is some evidence that hyperthyroidism does in the healthy animal increase the adrenalin load of the chromophil tissues. The adrenalin load, however, is so easily altered by a variety of circumstances that it signifies little in itself. The alleged increase of adrenalin in the blood of animals suffering from hyperthyroidism is neither proved nor disproved. The evidence is untrustworthy. There is greater unanimity in ascribing to the thyroid hormone an activating influence upon the structures which are amenable to adrenalin. This sensitizing action of thyroid may explain the phenomena of Graves' disease which have been attributed to an increase of adrenalin in the blood. It does not exclude the possibility that an increased secretion of adrenalin may actually occur in this condition. A specific action of thyroid in stimulating the secretion of adrenalin, and in sensitizing the structures amenable to its action, though not improbable, is not satisfactorily proved. Pituitrin has a similar action in sensitizing certain structures to the action of adrenalin, and further experimental work may extend the similarity. Hypothyroidism is shown to have no effect upon the adrenalin load of the suprarenals, but here again no definite conclusions as to the absence of a specific stimulus can be drawn, for we know nothing about the extent of the requirements of the body for adrenalin in this condition. The theory that one endocrine gland exercises a specific influence upon another only touches a part of the question. The changes in metabolism which occur when any gland is disturbed in function must have a widely spread effect. Many of the metabolic changes undoubtedly take place in the liver, and it is unreasonable to suppose that this organ takes no active part in the problems presented by the ductless glands. Hyperthyroidism provokes such gross changes in the organs of the albino rat that one is drawn to look for the explanation of its effects in the products of a disordered metabolism. Noël Paton has emphasized the importance of the endocrine organs as regulators of metabolism. The investigation of the substances normally formed in the body, and the influence which the ductless glands have upon them, provides a line of research which may eventually lead to the establishment

of the endocrine glands as important factors in the regulation of the general metabolism of the body.

Revue médicale de la Suisse romande.

November, 1920, xi, 11.

Etiology of Goiter.—Boitel makes a very thorough contribution to this subject, which includes original work and maps. He reaches relatively few conclusions, his research being largely limited to goiter in one canton, that of Vaud. He finds the distribution of the disease in that canton to be very irregular. There is at least a coincidence between incidence and soil, for the least incidence is on the Jura mountains, especially on the flank, while the greatest is in the valleys of Broye and Mentue. This kind of contrast is to be seen in other goiter countries. Heredity is evident in 47 per cent. of cases. There is no evidence that autochthons suffer more than late comers. The distribution differs entirely from that of typhoid fever, both being supposedly water-borne affections. City dwellers are but slightly less affected than rural dwellers. There is as yet no proof that the disease is due to lack of iodine in the environment. Hunziker's dictum that the disease flourishes best at the altitude 600-1000 meters is not upheld. We have no basis for a causal therapy.

Famine Osteomalacia.—Cramer and Schiff consider this subject *in extenso*. The supposition is that the nature of an endocrine malady should be inferred from the treatment, and all observers insist that the nourishment should be abundant and varied. Subjects respond rapidly enough to show that the disorder is not deep seated. Calcium chloride, phosphorized cod liver oil, various other oils (sunflower), strontium and adrenalin have all been used, so that the treatment closely resembles the modern treatment of rickets. But plenty of good food and mineral food are sufficient for a prompt cure—several weeks.

La Presse Médicale.

December 11, xxviii, 91.

Hemoclastic Crises in Hepatic Insufficiency.—Widal, Abrami, and Iancovescu refer to the new exploratory test of hepatic insufficiency—the so-called digestive hemoclasia. It is based as follows: In the normal subject partly disintegrated proteins derived from the food enter the portal circulation and are arrested in the liver, for if they enter the latter in their heterogeneous admixture the blood suffers a hemoclastic crisis. In hepatic insufficiency the latter takes place. An immense amount of labor has been required to demonstrate these facts, and one is entitled to ask just what proteins are responsible for the crisis. It is safe to state that a mixture of amines is involved. Feeding subjects with hepatic insufficiency with certain crude proteins will produce the crises, but thus far we find no reference to any individual amines. The test shows that in very many clinical affections the liver is insufficient, and the author cites in succession cases of so-called cardiac liver, cirrhoses of various types, icterus of the most varied origin, the toxic action of neosalvarsan and chloroform, various acute infectious diseases, biliary lithiasis, diabetes, chronic nephritis, latent hepatic disease as in alcoholism, pelvic surgical affections, amebic dysentery, etc. Very small amounts of protein are able to produce these crises. One glass of milk has done it, and in a diabetic a little sugar. If a number of heavy drinkers are tested some will show latent hepatic insufficiency, others will not. A drinker for forty years still showed intact hepatic cells. Once immune always immune seems to be the rule in such cases. The subject is a promising one, but it is too early to announce it as a great advance in medicine. The blood counts are not discussed in this paper.

Rarity of Epidemic Hiccough in Women.—Achard and Pouillard mention this fact which has also been seen by others. The incubation period is shorter and the affection less developed. In a girl of 17 the hiccough seemed incomplete and limited to an inspiratory spasm of the diaphragm, chiefly upon the left side. This infrequency would seem to exclude a hysterical element, although there has never been any reason to suspect one in the present epidemic.—*Le Progrès Médical*.

Book Reviews.

FUNCTIONAL NERVE DISEASE, an Epitome of War Experience for the Practitioner, Edited by H. CRIGHTON MILLER, M.A., M.D., late Consulting Neurologist 4th London General Hospital. New York: Oxford University Press, American Branch, 1920.

Dr. Crighton Miller has presented the view of ten experienced men in dealing with war neuroses. The object is that while these states were exposed by the stress of war, their factors during peace should be realised as existing potentially in the practice of every practitioner. The hope is that a class of cases in which instruction is not given to the ordinary medical student, may receive due consideration in regard to etiology and treatment. The various writers present different points of view, but while physical therapeutics had to give place to suggestive therapy the latter had to be directed by the method of Psychoanalysis. Really treatment has to be directed to the causes of the trouble and the truly analytical method proved the means of dealing comprehensively with the variety of cases. Briefly the argument is that the psychoneuroses result from disharmony of the mind. This leads to amnesia and loss of control by the personality. Analyses of the mind, whether hypnotic or by association and association-reaction, with the content of dreams, are the chief aids, and then the readjustment may be made. This is aided by all the physical and mental reeducative and reconstructive processes which have been used. The book is an effort to deal by common-sense methods with a class of cases which have been to a considerable extent misinterpreted. The apparent divergence between the various authors does not militate against the general principles of the treatment, for in the principles all are agreed.

LE DIABÈTE SUCRÉ. Par DR. MARCEL LABBÉ. Paris: Masson & Cie, 1920.

This volume of 376 pages is the result of many years of study. The disease is divided into two types in accordance with the presence or absence of denutrition. The reader is naturally interested in the attitude of the author toward the Guelpa-Allen-Joslin treatment of the disease. His surprise will naturally be great to find that this aspect of treatment is almost wholly ignored, even under the head of acidosis on page 258 the three sponsors of the fasting treatment are disposed of in a few lines. Such studied indifference does not make a favorable impression; it is as if the book had been written a dozen years ago instead of recently and we more than suspect this to be the case. There is reason for the suspicion that the book was written long before the war and its publication indefinitely held up. Most Frenchmen are jealous of the credit of Guelpa in connection with priority in the fasting treatment but Labbé ignores him no less than his American rivals.

GRUNDZÜGE DER BEHANDLUNG VON HAUT- UND GESCHLECHTS KRANKHEITEN dargestellt von DR. LEOPOLD PULVERMACHER. Berlin and Vienna: Urban & Schwarzenberg, 1920.

This volume of pocket size and flexible covers seems designed especially for students. Of the 249 pages 188 are devoted to cutaneous diseases. The organic arsenicals receive but 8 pages *per se* but under the head of combined treatment old and new salvarsan receive additional attention. Under the treatment of skin diseases carbonic acid now receives but a paragraph. Facts of this sort are apt to suggest that many works now appearing in Europe were written before the war and are only now coming to light.

LES MUTILÉS DE LA GUERRE. Par DOUGLAS C. McMURTRY. Ancien Directeur du Red Cross Institute for Crippled and Disabled Men. New York: Avec une Introduction par le Dr. MAURICE BOURRILLON, Président du Comité Permanent Interallié pour l'Étude des Questions Intéressantes les Mutilés de la Guerre. Paris: Masson et Cie, 1920.

This volume is a translation of the author's work "The Disabled Soldier," so well and favorably known to American readers. The preface contains an appreciation of the author's prodigious activity and capacity for

work and styles him justly a man "of heart and of toil."

LE LAIT CONDENSÉ. Par Dr. P. LASSABLIÈRE. 2d édition, revue et augmentée. Paris: A. Maloine et Fils, 1920.

This little work has been awarded both the Prix Jeunesse and the Prix Monthyon for 1920. The author is the chief of the laboratory of the Faculty of Medicine, Paris. The book is a monograph of 150 pages on the subject of condensed milk. The subjects in detail are history, manufacture, chemical composition, food value, bacteriology, value in sanitation, physiological value, clinical value, relative indications for use in children and adults, therapeutic uses, etc. The book makes an appeal to many classes of readers, as dietitians, pediatricists, collectors of monographs, etc.

MARINE HYGIENE AND SANITATION. A Manual for Ships' Surgeons and Port Health Officers. By GILBERT E. BROOKE, M.A. (Cantab.), L.R.C.P. (Edin.), D.P.H., F.R.G.S., Chief Health Officer, Straits Settlements Medical Department, Port Health Officer, Singapore. Lecturer in Hygiene at Singapore Medical School, Author of "Tropical Medicine, Hygiene, and Parasitology," "Essentials of Sanitary Science," "Aids to Tropical Medicine," etc., etc. Formerly Ship's Surgeon to various shipping companies, also Health Officer and District Commissioner, Turks and Caicos Islands, West Indies. New York: William Wood and Company, 1920.

This is a book of an unusual type; it contains a large amount of the miscellaneous information which a Ship's Surgeon so constantly needs. It is a manual of "sailing directions" for the doctor, and it is written in as plain and colloquial a manner as possible. Throughout the volume one is struck with the author's inexhaustible fund of information, shrewd common sense, and general knowledge of human nature; and if a Ship's Surgeon once gets possession of the book, there is no possible excuse for his putting it down until he has read and enjoyed a large part of it. The author has had a wide experience, and many a novice will find his own difficulties and doubts solved in this chatty volume. It is assumed that the Ship's Surgeon possesses not only sound professional ability and judgment, but also an inexhaustible fund of good nature and tact; and the author wisely adds:—"A man without a saving sense of humor had better steer clear of the billet altogether."

DIATHERMY IN MEDICAL AND SURGICAL PRACTICE. By CLAUDE SABERTON, M.D., Hon. Radiologist to the Harrogate Infirmary, and to the Royal Bath Hospital, Harrogate. With 33 illustrations, New York: Paul B. Hoeber, 1920.

This book is obviously a compilation from various authors and with facts culled from their experience as well as from the writer's own. It deals accurately with the principles of Diathermy and it gives careful instructions as to its application. Here and there it makes excursions into the application of general high frequency currents as well as the essential practice of diathermy. Still the impression left on the mind is that diathermy is of so wide an application as to be nearly a "cure-all"; and this is a pity, for the author has set out his case well and fairly and has given a full bibliography. In this last it is an improvement on books of similar character and it is right up to date.
